

This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

- + *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.
- + *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.
- + *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.
- + *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at <http://books.google.com/>

A
CYCLOPÆDIA
OF
THE PHYSICAL SCIENCES.

Valuable Works of Reference.

Price 21s. Each

THE COMPREHENSIVE DICTIONARY OF BIOGRAPHY;

Embracing a Series of ORIGINAL MEMOIRS of the most DISTINGUISHED PERSONS, Living and Dead. With Steel Portraits and Numerous Engravings. Royal 8vo, half-bound.

THE LIBRARY GAZETTEER;

Or, DICTIONARY of PHYSICAL and POLITICAL GEOGRAPHY. With an INTRODUCTORY TREATISE on PHYSICAL GEOGRAPHY, by JAMES BRYCE, LL.D., F.G.S. Maps, and Numerous Engravings. Royal 8vo, half-bound.

MANY THOUGHTS ON MANY THINGS:

A COMPLETE MORAL, RELIGIOUS, and LITERARY TREASURY. By HENRY SOUTHGATE. Second and Cheaper Edition. 4to, cloth, gilt edges.

A CYCLOPÆDIA OF THE PHYSICAL SCIENCES.

Edited by J. P. NICHOL, LL.D., with the assistance of eminent Scientific Men. Second Edition, revised and greatly enlarged. With numerous Illustrations. One large Volume, 8vo, cloth.

A
CYCLOPÆDIA
OF THE
PHYSICAL SCIENCES,

COMPRISING

ACOUSTICS, ASTRONOMY, DYNAMICS, ELECTRICITY,
HEAT, HYDRODYNAMICS, MAGNETISM, PHILOSOPHY OF MATHEMATICS,
METEOROLOGY, OPTICS, PNEUMATICS, STATICS,
&c. &c.

BY

John Nichol
J. P. NICHOL, LL.D.,

PROFESSOR OF PRACTICAL ASTRONOMY IN THE UNIVERSITY OF GLASGOW,

WITH THE ASSISTANCE OF EMINENT SCIENTIFIC MEN.

MAPS, ENGRAVINGS, AND NUMEROUS WOODCUTS.

Second Edition, Revised and Enlarged.

LONDON AND GLASGOW:
RICHARD GRIFFIN AND COMPANY,
Publishers to the University of Glasgow.

1860.

TO THE
VERY REV. DUNCAN MACFARLAN, D.D.,
PRINCIPAL OF THE COLLEGE OF GLASGOW,
&c. &c.

REV. AND DEAR SIR,

I do not know to whom a volume, intended to assist the Student in his progress in any department of Science or Literature, can be more fitly inscribed than to you. And your consent that I prefix your name to this Cyclopædia is the more cherished by me, because, while it enables me to have the honour of referring to the value of your watchful and enlightened superintendence of the University to which we belong, it also allows me the privilege of declaring the respect, esteem, and affection with which I am,

REV. AND DEAR SIR,

Your obedient Servant,

J. P. NICHOL.

OBSERVATORY,
GLASGOW, 30th January, 1857.

PREFACE.

THE volume now offered to the Public is, so far as I am aware, the only English one, containing—within a moderate compass—so large an amount of information concerning the condition and progress of Physical Science, and presenting, at the same time, every facility as to *reference*. I earnestly and respectfully hope therefore, that it will prove useful, especially to the Student. That it is what a book with such a title ought to be, I do not in the least imagine. Few living authors are capable of producing an adequate “CYCLOPÆDIA OF THE PHYSICAL SCIENCES.” The time required to compose such a book, in the hands of even the best informed and readiest writer, would extend over a far larger space than our modern rapidity of Discovery and the press and hurry of modern Publication, will allow; and the difficulty of obtaining the right kind of assistance can be appreciated only by those who have required to seek it.

I shall not specify the defects of this volume, either as regards proportion or execution; for, they are apparent enough. I believe however, that I know them well; and, assuredly, I could have wished, for the sake of the Reader, that circumstances had permitted me to present him with a volume free from such defects. It is much more agreeable to me, to have the opportunity of thanking a few of the eminent friends to whose kindness it owes its excellences. The philosophical Student of Mathematics will find a series of letters on QUATERNIONS (in the Text and Appendix) which SIR WILLIAM ROWAN HAMILTON alone could have written,—so thorough are they, and so lucid. These remarkable letters will make known, probably for the first time, to many mathematical Inquirers on this side the Irish Channel, the nature, the power, and fertility of the method of Quaternions; and I believe they will be regarded in after times, with the interest with which we refer now to the best parts of existing scientific literature of this description, rich though that is.—A second most valuable contribution is due to the REV. DR. ROBINSON of Armagh. This very distinguished Astronomer and Physicist kindly wrote, at my request, the article SPECULUM; an article in which is presented, to the general Reader—also, I believe, for the first time—a critical account of the inventions and processes by which LORD ROSSE and others have succeeded in bestowing on the Reflecting Telescope a degree of perfection and a grasp, until recently quite un hoped for. Dr. Robinson's article, while succinct, is yet so full and precise, that I am fain to indulge the hope of its stimulating and guiding further enterprise.—To ARCHIBALD SMITH, Esq. of Lin-

coln's Inn, my best thanks are offered for an ample and very instructive article on question with which his name is intimately associated, viz., the disturbing effect of the *Magnetism of Ships* on the COMPASS.—My colleagues, PROFESSORS WILLIAM THOMSON and RANKINE, have also given me their assistance. To the former I owe many invaluable suggestions, besides his notice on THERMO-MAGNETISM—(a subject which, in its present form, is almost wholly a creation of his sagacity and genius)—and his *Essay on the Appendix* on the ELECTRIC TELEGRAPH: and the originality and power of the latter will be recognized in articles HEAT, ELASTICITY, VAPOURS, STEAM ENGINE, &c.—I am deeply indebted to my friend DR. JOHN TAYLOR of the Andersonian University. He has written many articles on Electricity, and on those portions of Optics that have relations with Physiology and with Photography. Nor do these contributions comprehend the amount of my obligations to him.—I have been favoured, besides with aid from MR. J. R. NAPIER of Glasgow; from MR. R. RITCHIE, C.E., and MR. JAMES ELLIOT, of Edinburgh; and from MR. KER, one of our recent BREADALBANE EXHIBITIONERS: but I must emphatically specify the services of another and younger Breadalbane Exhibitioner—MR. WILLIAM JACK, now of St. Peter's College Cambridge. This well-informed and very promising Student has contributed numerous separate articles; and I must say farther, that without the help of his untiring industry, it would have been difficult for me to have gone through the almost intolerable labour inseparable from the producing of a volume like the present one.

Turning from *Men to Books*, I shall candidly confess, that when I assented to MR. GRIFFIN'S proposal that I should edit such a Cyclopædia, I had it in my mind that I might make the *scissors* eminently effective. Alas! on narrowly examining our best Cyclopædias, I found that the scissors had become blunted, through too frequent and vigorous use. One great exception exists, viz., the *Penny Cyclopædia* of CHARLES KNIGHT. The cheapest and the least pretending, it is really the most philosophical of our scientific dictionaries. It is not made up of a series of treatises, some good and many indifferent, but is a thorough *Dictionary*, well proportioned, and generally written by the best Men of the time. The more closely it is examined, the more deeply will our obligations be felt to the intelligence and conscientiousness of its Projector and Editor.—But I acknowledge many debts to various separate works in different departments of science. I have spoken frequently in the text of the volume on *Practical Astronomy* by PROFESSOR LOOMIS of New York;—once more, I beg to recommend it as the best work of the kind in the English tongue. May I record the wish, that Professor Loomis would translate the invaluable volumes of BRÜNNOW and SAWTCH? A new Mathematical Dictionary by MESSRS. DAVIES and PECK has recently been published in New York. It is a great advance on BARLOW'S Dictionary, and has many claims on the attention of the Student. I have extracted a few articles from its pages: as I have done also from the useful and pleasing introduction to the *Modern Geometry*, by PROFESSOR MULCAHY of Galway.—In Physics, there is not at present, in English, any standard *general* work. To DR. LLOYD'S Lectures on the Theory of Light, I have been largely indebted, especially in the article on THIN PLATES, and part of the article on DOUBLE REFRACTION. SIR DAVID BREWSTER'S recent volume on Optics has often guided me in the exposition of phenomena; as well as his original Memoirs: and of course the *Répertoire* of the ABBÉ MOIGNO has proved a constant source of information. It is

scarcely necessary to allude to the services—of which I have freely availed myself—rendered by the Abstracts of Memoirs, &c., which are found in our English and Foreign scientific periodicals, viz.:—*The Edinburgh and London Philosophical Magazine*, the *Annales de Physique et Chimie*, and *Poggendorf's Annalen*. Finally, let me acknowledge the obligations I am under to the exquisite and instructive Physical Atlas of ALEXANDER KEITH JOHNSTON, Esq.

The statement now made may convince my Readers that I have not neglected appliances likely to afford adequate aid. I wish I could have lessened farther the very large amount of what—as a glance over the contents of this Cyclopædia will show—must rest on my own responsibility. Owing to the ceaseless but irregular pressure necessarily falling on the Editor of such a volume, I have not been able to restrict myself to the treatment of those parts of Physical and Mechanical Science, with which previous acquirement had rendered me rather familiar: nay, I have, in some cases, felt obliged to delegate the treatment of portions even of these.—So much for the building-up of this book.—May I solicit that it be received in the spirit in which it is offered?

The advantages of Alphabetical arrangement in such a work, are undoubtedly largely counterbalanced by the broken, incomplete, and therefore unsatisfactory character of many of the separate articles. This inconvenience has been obviated, as far as practicable, by distinct references from article to article: and several essential references omitted in the text—are indicated and supplied in the preliminary table of *Errata*.—I must allude however to two matters of greater consequence. It has not been possible to do justice—even comparative justice—to the Inquirers who have advanced and are rapidly advancing all departments of Physics. When the names of special Inquirers are mentioned, it is because of some very noticeable peculiarity in their relations to the subject. I should indeed have rejoiced had space permitted the introduction of Historical considerations, or of attempts to appreciate and offer tribute to the worth of Contemporaries. Neither have I desired to pronounce absolutely concerning those few physical questions now under active discussion. The writers of the articles connected with such questions may not have thought fit, in every instance, to conceal their *leanings*; but the intention has always been to state fairly the nature of the conflicting views.

J. P. N.

OBSERVATORY, 30th January, 1857.

PREFACE TO THE SECOND EDITION.

It is necessary to state the circumstances under which the Second Edition of the **CYCLOPEDIA OF THE PHYSICAL SCIENCES** is issued. The revised sheets were passing under the Author's hand when it was arrested by death in the midst of this, his latest effort; but such arrangements had been made for completing the work, that the Editors have had only difficulties of detail to surmount in carrying into execution what they knew to be the Author's intentions.

A few errors in the First Edition have been corrected, some omissions supplied, and several articles materially enlarged, to make room for the more recent results of experiment and speculation. Among other subjects which have received a more extended treatment, it is right to specify that of "Equations," which has been ably and fully expounded by MR. KER. The short notice of "Electrical Egg," which formerly appeared, has been replaced by an article of considerable length, in which the subsequent important discoveries under that head are discussed. PROFESSOR WILLIAM THOMSON has kindly revised and amplified his articles on "Electrometer," and the "Electric Telegraph." A valuable addition has been made to that on Fraunhofer's lines in the account which PROFESSOR STOKES has given of his discoveries with reference to the Invisible Spectrum.

Several entirely new articles have been added. PROFESSOR RANKINE has supplied those on the "Conservation of Force," and the "Skew Arch." We are indebted to DR. TAYLOR for an interesting essay on the "Atmospheres of the Planets;" to MR. HEMMING, of London, for a history of "Decimal Coinage;" and to MR. P. E. DOVE, for an article on "Rifles."

The whole Work has thus been considerably increased; and we have only to express a hope that enough has been done to render it yet more worthy of the support with which it was formerly favoured.

GLASGOW, *January*, 1860.

SUPPLEMENTARY REFERENCES.

[The Reader is requested to insert, or notice, the following references from Text to Appendix.]

HEATING OF BUILDINGS, page 431. See Note concerning VENTILATION in Appendix.

IMAGINARIES, page 458. See IMAGINARY EXPRESSIONS in Appendix.

LIGHT, VELOCITY OF, page 506. Somewhat discrepant statements are found in various articles in reference to the actual velocity of light. The best *Astronomical* determination of it is still perhaps that by Struve, which gives it as 191,515 miles per second. The physical determination by Fizeau gives a higher number—nearer to the original one of Römer. But whatever the excellence of Fizeau's experiments, we must take our absolute determination from astronomical methods.

STEREOSCOPE, page 812. See Appendix.

The following Articles will be found in the APPENDIX:—

ATMOSPHERES OF PLANETS.	SCREW.
PHASE.	STEAM.
PHOSPHORESCENCE.	STEAM-BOILER.
POLYNOME.	UNIVERSAL INSTRUMENT.
PULLEY.

CYCLOPÆDIA

OF THE

PHYSICAL SCIENCES.

ABE

Aberration: a term used to designate three optical phenomena of much importance. They are:—

(1.) *Aberration of Light*; a very curious apparent displacement of the stars; one, to which any object exterior to the earth, and unaffected by the motion proper to that orb, would appear subject. Its nature may be illustrated, simply, as follows:—Imagine a shower of rain, falling, in the absence of wind, perpendicularly; every drop would evidently fall right through the axis of a tube held right up or in a perpendicular position,

provided that tube were at rest. The vertical position of the tube would thus correspond with the direction of the rain, and indicate it. But if the tube were in motion, say in the direction of *B*, the rain drop entering at the centre of its top at *B* would no longer come out at the centre of the end at *A*: on the other hand, it would strike, or tend to strike, before issuing, on the side *A B* of the tube. In such a case, if an observer or an experimenter desired to catch, at the middle of the tube's end *A*, the drop which entered at the middle of the end *B*, he would require to incline the tube towards the direction of the tube's motion, as below. And the degree or amount

of the requisite inclination would evidently depend on the swiftness of the tube's motion, and the swiftness of the fall of the drop. Now, should

an observer in this case require to judge of the direction in which the drop falls, by the direction of the tube, he would evidently fall into great error should he suppose the direction of the former to be identical with the direction of the latter; or if he did not apply a correction, for the purpose of avoiding the error occasioned by the forward motion of the tube.—The circumstances we have just imagined, are precisely those under which we are constrained to look at any object

ABE

unaffected by the motion of the earth. Whatever *light* is, it is propagated in straight lines with a definite velocity of 195,000 miles per second; and thus is in so far analogous to a falling rain. And when we look at a star, we are *not* at rest. The earth partakes of various motions,—the two leading ones known to us, being its *annual* motion in its planetary axis, and its *diurnal* rotation. The direction or inclination of the tube or telescope through which we look, therefore, can never correspond exactly with the direction of the light coming from any star or external object; and if we judged the direction or place of the latter to be identical with the direction of the former, we should go wrong. Further still, the error in question would be a *constant* and *uniform* one, if the motion of the earth were *always* in the same direction; but as we move in a *curve* around the sun, that direction must be always varying: i. e. the star, as determined by the position of the observer's telescope, must, during the course of the year, seem removed by small quantities towards *each side* of its *real place*. In fact, every star appears to describe a small annual ellipse around its true place; the major axis of which is $20\frac{1}{4}$ " of space. This ellipse, however, is described irregularly, owing to the varying velocities of the earth; but as its entire character is now ascertained within very small limits of error, the *correction* is easily made.—The *diurnal* aberration, or that depending on the *rotation* of the earth, is very small, and is also accurately determined.—It will readily occur to the thoughtful student, that other aberrations of this kind may exist,—depending, for instance, on that motion of translation through space to which we cannot doubt that the sun, with all his planets, is subject: the determination of the amount of that, and of its corresponding *aberration*, is one of those feats whose accomplishment will inspire and reward the ambition of future times.—The discovery at once of the fact and cause of the annual aberration is due to the illustrious Englishman, Bradley. The best practical discussion of it, we owe to a recent continental astronomer; one whose eminent taste and exact genius place

ABE

him by the side of Bradley—the lamented Bessel. See the *Tabula Regiomontana*.—The explanation now given merely assumes the fundamental fact that light is transmitted in straight lines. But considerable difficulty arises so soon as we accept the modern physical theory of Light. Under the doctrine of Undulations, the direction of propagation, or the direction in which the luminous object as seen, is normal or perpendicular to the front of the wave; and the theoretical question is, in what manner a wave, propagated through a motionless Ether, is affected by the motion of a body such as the Earth, sweeping through that Ether? Modification clearly must take place, else there were no aberration whatever: but what is that modification? how can it be reconciled with the geometrical theory of the propagation by waves? The difficulty evidently consists in determining in what manner the direction of the normal of a wave can be affected by the motion of the body which that wave reaches. Professor Stokes has fully discussed this problem; nor can anything at present be added to his memoirs and those of Professor Powell. He supposes that the Earth and Planets *drag* along with them a portion of the Etherial Medium; so that while the Ether at their surfaces is at rest with regard to these surfaces, its motion gradually diminishes with distance, until it takes on the repose of the universal Ether beyond. All aberrations may be explained on this hypothesis—even that which may, in after ages, be found dependent on the motion of translation of the Sun. Other contributions have been made to this subject—for instance, those of M. Radické.—For Mr. Stokes's memoirs, see *Transactions of Cambridge Philosophical Society*.

(2.) *Aberration of Refrangibility*. White light is composed of a number of heterogeneous rays, of different colour. Their refrangibility is unequal, and, therefore, when they traverse a lenticular glass, they have on its axis as many sets of foci as there are colours. The images produced at these points are superimposed, more or less, and the edges fringed with indistinct colouring. The aberration holds, both in length and breadth, the less refrangible rays, unite at foci farther away than the others, and constitute the aberration in length. The larger cover to some extent those whose light is most powerful, producing an indistinctness of colouring, and sometimes a sort of variegated ring. This gives rise to the aberration in breadth. See ACHROMATIC TELESCOPE (*q. v.*)

(8.) *Aberration of Sphericity*. Consider a spherical cap, forming a concave spherical mirror. The opening of the mirror will be the angle formed by two radii from the centre of the sphere to two extremities of the diameter of the rim. Let us suppose a luminous point situated on the axis, that is, the line joining the centres of all the concentric circles of the cap, with the centre of the

ABS

sphere of which it is a part. The rays emitted by this point will be reflected and reconcentrated at one or more points of this axis. If the angle which all the rays make with the axis be under 8° or 4° , they will be reflected upon one point or nearly so, and that point is called the focus. But if the range of the angles of emission be sensibly higher than this, there would be a *line of foci*; one point serving for reconcentrating all the rays upon one of the concentric circumferences of the cap; and the focus for each such circumference being nearer the cap, the greater that circumference is. We would have thus a *line of images* of the luminous point; and this effect termed the *aberration of sphericity*. See TELESCOPE, REFLECTING.

Absorption: etymologically, a “drinking in;” technically, the physical assimilation of one substance—*ponderable* or *imponderable*, according to still current phraseology—by another substance; as if the first substance got retained among the pores of the second. There are three classes of phenomena to which the word *Absorption* is usually applied.

(1.) *Absorption of one Ponderable by another*—for instance, *gases by water or charcoal*. See *Cyclopædia of Chemistry* passim. Absorption of this description seem to have been no unimportant agencies, in modifying even the solid crust of our globe.—In reference to the absorption of gases by liquids,—by far the most important of all cases of absorption,—the recent researches of Bunsen leave little to be desired. The special phenomena to be observed and the problem to be realized are as follows:—“When a gas and a liquid, exercising no reciprocal chemical action, are placed in contact, a portion of the gas disappears, or is absorbed by the liquid. The quantity absorbed depends on the temperature of the two masses, and on the nature of the gas and of the liquid;—the problem is to determine the part played by each of these elements in the production of the observed effect.” We subjoin Bunsen's leading results. (1.) Suppose, *first*, that a liquid of unit-volume, in contact with an *indefinite* atmosphere of a determinate gas, it will always absorb the same quantity of the gas, provided the pressure and temperature remain the same. Taking the temperature and pressure at zero (temperature at 32° and pressure 30 inches), the numerical expression denoting the quantity absorbed is termed the *coefficient of absorption* of that gas by the liquid. If the temperature is constant, and w the weight of gas absorbed, under the zero pressure, the weight of the quantity absorbed under any other pressure, P , is found to be $w \frac{P}{30}$. Any other volume u of the same liquid will, under such circumstances, absorb $u \cdot w \frac{P}{30}$.—Again, let the indefinite atmosphere be composed of different

ABS

gases, whose coefficients of absorption are respectively $a, a', a'', \&c.$ If $v, v', v'',$ represent the proportions of each gas in the mixture, it can be shown that $av, a'v', a''v'', \&c.,$ are the measures of the volumes of the different gases absorbed by the liquid under any given pressure; and, consequently, that in a unit-volume of the compound gas absorbed, the following quantities of the several gases will be found, viz:—

$$\frac{av}{av + a'v' + a''v'' + \&c.}, \frac{a'v'}{av + a'v' + a''v'' + \&c.},$$

(2.) Secondly, If the superposed atmosphere be limited, the pressure will change as absorption proceeds, and the problem becomes somewhat more complex. Suppose that the atmosphere at first, under the pressure P , contained v and v' volumes of two gases, whose coefficients of absorption at zero temperature are a and a' , and let x and x' designate the unknown final pressures of the two elastic fluids. The volumes absorbed, reduced to the pressure P , will evidently be

$$\frac{avx}{P} \text{ and } \frac{a'v'x'}{P}.$$

At first, one of the gases under the pressure P

Nitrogen,	$c = 0,020346 - 0,00053887 t + 0,000011156 t^2$
Hydrogen,	$c = 0,0193$
Ethyle gas,	$c = 0,031474 - 0,0010449 t + 0,000015066 t^2$
Gas from a marsh,	$c = 0,05449 - 0,0011807 t + 0,000010278 t^2$
Methyle gas,	$c = 0,0871 - 0,0088242 t + 0,0000608 t^2$
Carbonic oxide,	$c = 0,032874 - 0,00081632 t + 0,000016421 t^2$
Olefiant gas,	$c = 0,26629 - 0,00918631 t + 0,000188108 t^2$
Carbonic acid gas,	$c = 1,7967 - 0,07761 t + 0,0016424 t^2$

After exposing the theory of the subject in the general manner indicated above, Bunsen proceeds to develop certain valuable applications of his formula. Referring for his processes—which are exceedingly simple—to his second memoir, in the *Philosophical Magazine* for 1855, vol. i., we shall here make room for the more important of his results.—(a), Supposing that in the case of a mixed gas, the following quantities are known, viz:— a , the absorption-coefficient of the first gas; β , the absorption-coefficient of the second; V the common volume of both gases before absorption under pressure P ; V_1 the residual volume after the absorption under pressure P_1 ; and, lastly, the volume h of the absorbing water: then if

$$W = VP$$

$$A = (V_1 + ah)P_1$$

$$B = (V_1 + \beta h)P_1$$

we have

$$\frac{x}{x+y} = \frac{W-B}{A-B} \cdot \frac{A}{W}$$

and

$$\frac{y}{x+y} = \frac{A-W}{A-B} \cdot \frac{B}{W}$$

from which x and y , the original volumes of the

ABS

occupied a volume equal to v . There remains then unabsorbed a quantity capable of occupying, under the same pressure, a volume expressed by $v - \frac{avx}{P}$; and as this gas really occupies a volume $v + v'$ under the pressure x , we derive from the law of Mariotte the equation

$$v - \frac{avx}{P} = \frac{(v + v')x}{P}; \text{ whence,}$$

$$x = \frac{vP}{v + v' + av}.$$

The quantity of this gas not absorbed, therefore, is

$$v \cdot \frac{v + v'}{v + v' + av}.$$

And so of the other gas, or of any element of a more complex combination.—(3.) Bunsen next examines the effect of the variation of temperature, and, after elaborate investigation, he constructs a table, of which the following is an extract. It gives the coefficient of absorption of the gases by water under pressure 30 inches, and at any temperature t , Centigrade:—

two gases, reduced to pressure 1, may be determined. In the memoir referred to, the formula is tried on two unknown mixtures of hydrogen and carbonic acid gas; and for the sake of comparison, the same gas was analyzed by the ordinary endiometric methods. The following are the results: The first experiment gave—

	Hydrogen.	Carbonic Acid.
1. By endiometry, .	0.9246	0.6754
2. By absorptiometry, .	0.9207	0.6793

By the second experiment on other proportions of the same gases, Bunsen obtained—

	Hydrogen.	Carbonic Acid.
1. By endiometry, .	26.81	73.19
2. By absorptiometry, .	26.67	73.33

The correspondence in both cases is certainly sufficiently remarkable to establish the value of absorptiometry.—(b), But this mode of analysis may go much farther; it may determine also the nature of the component parts of an unknown gas, as well as their proportions in the compound, when once the absorption-coefficients of all the gases are determined. Bunsen justly remarks that any general re-agent, to distinguish between the constituents of a gaseous mixture, has hitherto been wanting. The quantitative composition of a gas

ABS

as determined by endiometry, is mixed up with hypotheses as to its qualitative constitution. "If," he says, "analysis shows the presence of a mixture of marsh gas and hydrogen, it is uncertain whether we are not experimenting upon mixtures of methyle and hydrogen, or of methyle, marsh gas, and hydrogen." It is, however, easy, by means of the law of absorption, to remove these doubts, for "the absorption-coefficients serve as re-agents which cannot be found in other modes of gas analysis—presenting the peculiarity that they not only show the qualitative, but, at the same time, the quantitative composition of the gas. Our author, indeed, develops easy formulæ, by which, should an unknown gas be a mixture of an unknown volume x with another volume y of another unknown gas, it is possible, after three absorptiometric experiments, to determine, *first*, what gases are present in the mixture, and, *secondly*, in what proportion they are present.—(c), Bunsen next lays down rules for determining, in the most precise manner, the alteration which a mixture of gases undergoes by contact with water; and he passes to consideration of those highly interesting phenomena which accompany the evolution of gas in mineral springs,—phenomena that cannot be fully understood, unless by help of the law of absorption. Passing over more delicate inquiries, it is plain, for instance, that in all springs that contain carbonic acid gas alone in solution (and these are by far the most common), the limit or maximum of the gas depends definitely on the temperature of the spring, the depth of its shaft, and the height of the spring above the sea. The pretensions of all springs can thus be rigorously tested. Sigwart, for instance, gave out that the "Fürsten Quelle" in Imnau contained 2,500 cubic centimetres in the litre; the maximum is only 1878.2. By the same unerring guide, we are led to determine the maximum amount of carbonic acid gas that can be carried down from the atmosphere to the surface of the earth, as well as the mode of its distribution over the different zones of terrestrial climate. This quantity diminishes as the temperature rises; and therein seems to appear an effort of nature to assist the tardy vegetation of the cold north by a richer nourishment, and by a sparing supply to keep the luxurious growth of the tropics within limits.—Bunsen proceeds with the rationale of the great productiveness of mould, rich in summer, and of the advantages derived by the agriculturist from breaking up his land. He promises to extend his researches farther,—to scrutinize the phenomena of the oceanic atmosphere and of the absorption of air by the blood.

(2.) *Absorption of Caloric or Heat.* The technical terms of the sciences generally originate in theories or hypotheses: they express not only the fact but some supposed explanation of it. But although it is often convenient to retain them after the discredit of the speculation in

ABS

which they originated, the student requires to on the watch lest they carry into his mind some what of those exploded notions, and thus afflict injuriously his train of thinking.—*Absorption Heat* meant originally as follows:—A ray beam of heat falling on any substance, part it enters that substance and warms it, or *absorbed*; while another part is rejected or reflected by that substance, and passes off through space. The class of inquiries for which it really stands, on the other hand, may be defined thus:—Different bodies exposed to the same heating influence become heated with various facilities,—there any law regarding such facilities, and that law connected with other relations of the bodies to the phenomena of heat? Two distinct inquiries demand attention,—the *first*, omitting reference to the opacity or transparency of bodies with regard to heat—their *athermancy* and *dithermancy*; and the *second* relating especially to these latter properties.—*First*. The general *absorbing*, or, as it has also been termed the *admissive* power of bodies with regard to heat, has been the subject of laborious investigation by Leslie, Dulong and Petit, Melloni, and more recently by Provostsaye and Desains. It seems to depend mainly on two elements,—the nature of the *body's surface*, and the nature of the *heating source*. 1. The nature and amount of the influence of body's surface, on its capability of being warmed, may be inferred from the following results, obtained chiefly by Provostsaye and Desains. The numbers represent the quantities absorbed of 100 incident rays of heat:

Lamp black	100
Black lead.....	100
Writing paper.....	98
Common glass.....	90
China ink.....	85
Rock salt.....	72
Silvered glass.....	27
Mercury.....	28
Polished iron.....	28
———— zinc.....	19
———— steel.....	17
Platina, slightly polished.....	24
———— in thin leaves.....	17
Tin	14
Mirror metal, polished.....	14
Brass, highly polished.....	7
Copper.....	7
Gold.....	5
Silver, polished.....	8

Numerical determinations of this kind are of high importance in the arts, and of easy application. The following general conclusion is, however, of higher interest. A heated body communicates heat in two ways,—through contact, or by that mode of influence from a distance, which has been called *radiation* or *emission*. Now, the *absorbing* or *admissive* quality of bodies, and their

ABS

radiating or emissive faculty, are *directly proportional*; a body when heated radiates with an energy exactly measurable by its facility in absorbing; a conclusion indicated by Leslie and established for all circumstances and all temperatures by Dulong and Petit. Experimental determinations of absorptive power, are thus determinations of the emissive power also.—2. This absorbing faculty of bodies varies to some extent with the nature and temperature of the source of heat; so that no numerical evaluation is precisely accurate unless in reference to one specific source of heat. Science is indebted to Melloni for the first exact presentation of this curious phenomenon. Its nature will appear in the following table; where the numbers in the vertical columns represent the relative absorbing powers of the substances named, when subjected to the specified sources of heat:—

Substance.	Lamp.	Incan- descent Platinum.	Copper at 750 degs	Cube at 212 degs.
Lamp Black, ...	100	100	100	100
Indian Ink,	98	95	87	85
Black Lead,	53	56	89	100
Bituminum,	52	54	64	91
Black Salt,	43	47	70	72
Polished Metal, ..	14	13.5	13	13

The variations are sufficiently striking. Melloni takes a theoretical view of the phenomena, and is attracted by analogies drawn from prevalent theories of light. Just as a ray of white light is a sheaf of various rays separable by means of their different refrangibilities—(see SPECTRUM)—so he imagines it with a ray of ordinary heat; each ray in the sheaf having its peculiar relation to the body on which it impinges. And as the heat issuing from different sources, and with different temperatures, may contain various proportions of these simple rays, the apparent anomalies expressed in the foregoing horizontal lines may thus seem explicable. It cannot, however, be conceded that Melloni's remarkable experimental results establish the truth of his theory.—*Secondly.* The term *absorption* has likewise been generally applied to that loss of radiant heat which occurs on its passing through bodies,—akin to the apparent loss of light on its passage through semi-opaque and coloured substances. Melloni has recently given to this class of phenomena the much more correct name of *athermancy* and *diathermancy*; nevertheless, we shall describe them under the old and better known terms. The following are the leading facts at present established. The quality of bodies which causes their absorption of heat, has no relation to transparency or opacity; that is, to the quality which causes their transmission or absorption of radiant light. For instance, rock salt has no power of absorption, being purely diathermanous, while a screen of alum absorbs a very large portion of the ray, especially if the source of heat be

ABS

of low temperature; black glass, too, and discs of quartz, would, with smoke, transmit no light, while they are much less absorbent of heat than alum. No body yet known is so perfectly diathermanous as rock salt; it absorbs no sensible portion of radiant heat, although the plate be an inch thick: all other substances absorb more or less of the transmitted beam; and the absorbed proportion varies with the thickness of the plates and the source of heat, according to very complex laws. Generally speaking, rays proceeding from sources of a low temperature, contain a large proportion of absorbable rays; and in regard to the thickness of the plate, the quantity absorbed increases rapidly as the thickness increases. To this increase, however, there is a limit; for after the plate attains a certain thickness, its power to absorb seems incapable of further augmentation,—as if—to recur to the words of our former theory—the sheaf of rays proceeding from each source were composed of elements variously absorbable, some being completely absorbed by plates of slight thickness, others yielding only to greater thicknesses, while the remainder resist all absorption. There is, in fact, a striking analogy between the phenomena of absorption of heat, when passing through media, not perfectly athermanous, and the transmission of radiant light through coloured glasses. For instance, light, which has passed through a red glass, is not further absorbable by red glasses, while a disc of violet glass will absorb or destroy it all; so, while additional thicknesses of alum absorb no more heat, the interposition of a thin plate of green glass will destroy the whole of the ray transmitted through a thin plate of alum;—the effects of the combination, or superposition of different screens, being, in either case, independent of the order of superposition.—Compare DIATHERMANISM, DIFFUSION, RADIATION, REFLECTION. Reference is also made to *Melloni's Remarkable Papers*, reprinted in *Taylor's Scientific Memoirs*.

(3.) *Absorption of Light.*—The subjects comprehended under the foregoing term, are the obscurest in all Optics. They have not been fully explored by experiment, and their theory is far from satisfactory. They may be ranged under three heads.—*First.* The *natural colour of bodies*, has until lately been attributed to an absorption. The white or natural solar ray being shown by the prism to be a sheaf of rays of different colours, it was supposed that every material substance has the faculty to absorb or appropriate part of the natural ray, and to reject or reflect the residuum; and, as this reflected residuum might consist of one primary colour, or any combination of primary colours, the notion offered a *prima facie* highly probable account of that infinite luxuriance of hue which distinguishes external nature. But the speculation will not stand the test of inquiry. Analyzed by the polariscope, the coloured light, reaching us

from material bodies, turns out not to be *reflected* but *refracted* light,—emanating, therefore, from the bodies' *interior*. And, still further, it is maintained, on grounds far from untenable, that the white or ordinary ray falling on any body which appears coloured, is really *reflected white*; so that there can be no decomposition of the ray, or one set of colours *absorbed* and another set *reflected*. The whole of this curious subject is discussed under COLOURS. It is certainly not proved as yet that a *bona fide* absorption has aught to do with the phenomenon.—*Secondly*. The term *transparency* is only relative. No body is so transparent that light passing through it, shall emerge, of the same quantity and quality, as when it entered. And the loss or modification which the ray undergoes is, in common language, termed *absorption*. One instance will suffice to illustrate the case. Through a piece of polished smalt blue glass, the colour transmitted is mainly blue. But to define the effects of transmission, it is needful to look not at the compound white light, but at the *spectrum*, through such a medium. If the glass be of extreme thinness, all the colours are seen, although the eye can recognize differences in their relative intensity. But when the thickness of the plate reaches the twentieth of an inch, we discern very striking and singular appearances. The spectrum seems no longer *continuous*, but consists of several detached portions, separated by broad black intervals; the rays filling these spaces in the perfect spectrum being in some way extinguished. If the thickness of the plate is increased, the black spaces become broader, till at length all the colours between extreme red and extreme violet are wholly destroyed. If these semitransparent media were perfectly transparent with regard to one primitive colour, and opaque to all others, the resulting phenomena would be simple; but as each thin medium is very imperfectly transparent with regard to any colour, and variously so with regard to the different colours, the phenomena of absorption are most complex; the same medium, when altered in thickness, appearing to transmit quite different colours. Take, for instance, a thin hollow glass wedge, and fill it with muriate of chromium; white paper seen through the thin edge will appear of a fine green, but as we look through a greater thickness, the green tint grows livid, and passes through a brownish hue to a deep blood-red. No one has contributed so much to the facts of this subject as Sir David Brewster. We owe to him especially the discovery of those remarkable powers of the nitrous oxide and other gases, to which we shall afterwards refer. Compare SPECTRUM.—*Thirdly*. The remarkable discovery by Fraunhofer of dark lines in the solar spectrum, naturally originated much novel and curious speculation regarding light. The phenomenon itself is fully described under FRAUNHOFER'S LINES, as

well as the effect of sundry gases just alluded to. Suffice it here, that its similarity to the so-called absorptive effects of *coloured glasses*, suggested at an early period of these inquiries a corresponding explanation: the absent rays we spoken of as *absorbed* by the gases in the *latter* case in the *former* by the *atmospheres* of the sun and other stars, from which the defective light issues. This theory naturally enough led to a strict examination of the solar ray during an annular eclipse; for then the light reaching the earth pierces through an unwonted thickness of our luminary's atmosphere: but as no unusual defect is discernible under such circumstances, no confirmation of the theory of absorption has hence been derived. In the opinion of many physicists a better explanation of the entire class of phenomena can be drawn, on the basis of the *Doctrine of Undulations*, from what is termed *Interference*. We shall discuss this fully under INTERFERENCE and COLOURS, *q. v.* The student is referred further to the numerous and most interesting researches of Sir David Brewster.

Accelerated Motion. The simplest mode of motion, as we conceive it, is when the moving body passes through equal spaces in equal time—a mode to which the name of *uniform motion* is rightly appropriated. It is evident, however, that many other modes are conceivable; for instance, the body may move quicker and quicker the longer its motion is sustained—in other words it may move over a greater space during the second *second* than it did during the first—over a greater space during the third *second* than it did during the second, and so on. Motion of this description is termed *Accelerated Motion*. It is clear, also, that an infinite variety of accelerations is possible inasmuch as we can conceive an infinite variety in the *laws* according to which the *acceleration* takes place; that is to say, during any *second* of time, the swiftness may be supposed increased only *as much* as during any other *second*, or, that increase may follow any other law. The case is much the simplest when the acceleration in a given time is *uniform*—the Motion being hence termed *uniformly accelerated motion*; and this is the only mode of accelerated motion presented to us by the simpler phenomena of the universe. When a heavy body falls from a height it is found to traverse 16 1-12th feet during the first *second* of its fall, and at the end of that *second* it has acquired a velocity capable of carrying it through 2×16 1-12th feet, or 32 1-6th feet during the next *second*. During that *second*, however, it is found to move through 32 1-6th + 16 1-12th feet, or 48 1-4th feet, so that it has been again *accelerated* by the same quantity as before, viz., 16 1-12th feet, and the same acceleration holds during every successive *second*. The *laws* of such a motion are easily determined. In the first place, geometrically. The motion which most closely resembles *uniformly accelerated motion* would be one, where

for very small portions of time, the body in question moves uniformly; and at the expiry of each of these portions receives a uniform increase of speed.

Suppose, for example, the line AG, representing the time in which a body moves, to be divided into smaller equal portions at B, C, D, E, F. Suppose, further, that for the whole space of time represented by AB, the body moves with the velocity BO (perpendicular to AB); and that at that moment it receives an increase of speed sufficient to make it move for the next interval with the velocity represented by NC. At the termination of this again, it will be set to move over the third interval with a velocity MD, and so on, the lines BO, NC, MD, LE, FK, each perpendicular to AG, and differing each from the one immediately preceding by an equal amount. The geometer will readily see that the summits A, O, N, M, L, K, H will be along one straight line. Those who are not acquainted with geometry may readily convince themselves by drawing the figure accurately. Since, then, we have here a case of motion very analogous to that whose laws we are seeking, let us observe the results. In all uniform motion, the space described is measured by the product of the number of units of time by the number of units of speed. If, for example, a body move uniformly for nine seconds, with a velocity such that it will move through three feet each second, it will have moved through 27 feet at the end of its course. Suppose, then, AB to be the number of seconds, and BO the velocity, the space moved through, would be measured by the product of AB and BO. But, this is also the measure of the space covered by a rectangle described with these, as adjacent sides. Hence, the number expressing the area of the rectangle may be taken as the number expressing the space of motion. Let us complete, then, the rectangles QR, PC, ED, SE, TF, XG, YG. Then, according to this law of uniform motion, the spaces described in the first, second, third, &c., portions of time will be measured by the numbers expressing the spaces QR, PC, ED, SE, TF, XG, which together make up AHG, together with series of small triangles A Q O, P O N, &c. Now, the geometer will again see that Q, P, R, &c., lie upon one straight line, and that these triangles are in consequence less when put together than the one figure A Q X H. Hence, the space described would be greater than the space AHG, and less than this in addition to A Q X H. So much, then, for this case of motion. It, however, is not exactly

the motion we wish to know about; but if we suppose the intervals of the increasing of speed smaller, we should have a closer resemblance to it. If the intervals were smaller, we would have a figure similar in every respect to the one given; the only difference being, that the breadth of A Q X H would be less. If we go on, continually making the intervals of acceleration smaller and smaller, we should approach infinitely near the case whose laws we are in search of. The results at which we would arrive would of course approach the result in that case; and if we imagine the intervals infinitely small, we may suppose ourselves actually to have arrived at a *uniformly accelerated motion*. The result in this ultimate case would be, that the space described would be measured by something between AHG and A Q X H added to a figure analogous to A Q X H. We easily see, however, that this figure constantly diminishes as BO diminishes, and that it again becomes smaller with the interval AB. Hence, where AB is infinitely small, A Q X H would become infinitely small also, and the space could only differ by an infinitely small quantity from AHG. The space described is thus measured by AHG virtually. The space, therefore, which is described by a body moving with a uniformly accelerated motion, from an initial velocity = 0, to any ultimate velocity, will be *half* that described in the same time by a body moving uniformly with the velocity to which it attains. The velocity (represented by the perpendiculars BO, NC, &c., at the points indicating the time) is evidently proportional to the time—that is, the velocity acquired at the end of four seconds will be four times that acquired at the end of one second. Finally, the space described in the time represented by AD, will bear to that described in the time measured by AG, the proportion of $AD^2 : AG^2$. This is evident geometrically; but the ordinary reader will readily comprehend it. In this case the length AD is half of AG, and the height DM is evidently half of GH, so that the space ADM will be $\frac{1}{2}$ of $\frac{1}{2}$ of AGH, or $\frac{1}{4}$ of it.—The method of the differential calculus is much more simple, and produces the same results. We shall not enter at all into an exposition of it, but merely give the steps. The velocity of any body moving irregularly will be found by dividing the infinitely small space traversed at the moment for which we wish to know the velocity, by the infinitely small time in which it is described. Now, in uniformly accelerated motion, this velocity will be $= a + gt$, where a is the velocity at the commencement, if any, g the velocity acquired in each second, and t the number of seconds after the commencement at which we note the motion. Hence $\frac{ds}{dt} = a + gt \therefore S = at + \frac{gt^2}{2} + C$, and if we commence to calculate motion from the point of starting, $S = at + \frac{gt^2}{2}$. We have included in these latter formulæ a case which is

not at first the same as that which we have hitherto considered. It is that of a body which commences to move with a velocity of its own, and which retains that velocity according to the law of inertia. In this case we have simply to consider what space would be passed through by the body due to the uniform motion which this force impresses upon it, and add it to the motion which the force of gravity has impressed upon it. — *Retarding forces* are also frequently spoken of. When we have a body in motion against a force constantly pulling it backward, we have to consider how far the body would move forward in consequence of the motion which the primitive force has impressed on it, and to subtract from it the effect of the retarding force, calculated exactly as above, as a *uniformly accelerating force* acting in the opposite direction. — The laws of *uniformly accelerated motion* are so simple, that natural philosophers have taken it, along with *uniform motion*, as the two standard species of motion. Wherever they wish to examine the consequences of any complex law of motion, they consider that motion as compounded, for an instant, of one which is perfectly uniform depending on the velocity at that instant, and of one uniformly accelerated. The details of the process of decomposition of motion belong to the higher dynamics, and we shall not enter into them.

Accelerating Force (technical). That force which is applied in any given case to the unit of mass is called the accelerating force. Its value depends on the proportion of an infinitely small increment of the velocity of any moment, to an infinitely small increment of the time ($\frac{dv}{dt}$). This expression is quite general, and applies also to the case of a retarding force, which is considered as a negative accelerating force, and is measured by the proportion of the increment of the velocity, (which in this case becomes negative, indicating a decrement), to the increment of the time.

Accidental Colours. See COLOURS.

Accidental Point. See VANISHING POINT.

Achromatic. In the article on the aberration of refrangibility, we have indicated that the different coloured rays of which white light is composed are differently refrangible. When, therefore, light direct, or reflected, passes through media, and becomes refracted before reaching the eye, the rays will be separated one from the other, and the image of the object become confused. Achromatism compensates for this, by making the luminous rays pass through different diaphanous substances, possessing different refracting and dispersive powers. By dispersion we mean—that there is a difference between the *indices of refraction* (*q. v.*) of the component colours of a ray of decomposed light, when passing through refracting media. The dispersive power of any substance is measured by the quotient of its dispersion by the mean index of refraction

(which depends on the mean light the spectrum), diminished by unity. There substances possessing unequal refractive powers with equal dispersive powers. The accomplishment of the aim of achromatism was long considered impossible. Newton himself thought that refracted light must always be decomposed. Euler pointed out that in the human eye—which is only an optical instrument—the difficulty was in fact overcome—and suggested the possibility of imitating the manner in which it was so. Hall, in 1733, constructed achromatic lenses, but did not publish his discovery. Dollond however, arrived at the same discovery in 1759 independently, and published it. He combined flint glass, or artificial crystal, in the arrangement of his lenses, with crown glass, or good ordinary window glass; and he found that by a suitable curvature, given to his object glasses, the image of an object might be seen through them distinct and colourless. It is easy to calculate what relation ought to subsist between the refracting angles of two substances, in order that, when used together they may neutralize the natural dispersion of the various coloured rays. Prisms, which transmit light without colouring it, are called achromatic and lenses are so, when they form in their focus colourless images. Achromatism is, however, not by any means complete. It has become sufficient in Art, for practical purposes; but it is still dangerous for the scientific observer to trust implicitly to it. The proportion of the partial dispersion of the two substances used is not constant through all their extent; and the indices of dispersion vary from one colour to another in the same luminous ray. The nearest approach to achromatic perfection, is made, when we employ a considerable number of prisms, of different substances.

Achronical (*a. not, χρόνος, time*). Denotes the point of time of the sun's rising or setting the commencing, or terminating, of a reckoning of time. In modern astronomy it is confined to the time of the sun's setting. A star, therefore, is said to rise or set achronically, when it rises or sets, at the moment of sunset. The word used to denote the moment of the sun's rising is *cosmic*; and the star is said to rise or set *cosmically* (*κόσμος, order, harmony*), when it does so at the moment of the sun's rising. When, again, the exact moments of the rising or setting of the star and sun are not identical, though nearly the same, the star is said to rise or set *heliocally* (*ἥλιος, the sun*).

Acoustics,—the physical science of Sound. As in every similar case, the *sensation* of sound must be separated from its material or physical *antecedent* or *cause*. These two phenomena although indissolubly connected, bear no resemblance to each other: a sound, as we generally understand it, has no more likeness to the material changes that necessarily precede the sensation, than a colour has to the vibrations of the ether or molecules that are the antecedents of

every sensation connected with sight. Now, it is with these material antecedents that physical science alone concerns itself. The fundamental proposition of Acoustics is this,—every sensation of sound is preceded by the vibrations of some external material body:—without this, as an antecedent, no sound is ever heard. The subject therefore may be divided into three chief parts:—I. A study of the general relations between the vibrations of external bodies and the sounds which we hear as their consequences. II. A study of the mode in which a knowledge or sense of such vibration is conducted to the human ear. And, III. A study of the different or special kinds of vibration which are effective in producing sounds. We shall take up these points in their order.

I. THE GENERAL RELATIONS BETWEEN SOUNDS AND THE VIBRATIONS OF EXTERNAL BODIES.

1. Let us first endeavour to form a distinct idea of what is meant by the vibration of an elastic body,—an object that may be accomplished by aid of a very simple illustration.

Suppose a piece of thin elastic metal, $A s$ —say a piece of the main-spring of a watch, having one end fixed at A , while the other at s is free. By a pressure of the finger bend the spring, so that the end s shall reach the position e , and then by removal of the finger set it free. The spring will rebound toward s , but it will not attain

rest on reaching its original position, $A s$. The velocity attained during the rebound will carry it to $A e'$, corresponding on the other side with $A e$. From this new position it will return with an equal rebound; and, precisely like the pendulum, it would, were its elasticity perfect and if no external obstruction existed, oscillate or vibrate for ever between these opposite positions. The time occupied by the spring between its quitting one position $A e$, and again returning to it, is termed the period of one oscillation or vibration; and it has been shown to be a law, that if the vibrations are small, that is, if e is not far from s , this period—(all other things remaining the same)—is constant; in other words, these vibrations are isochronous. Now, what we have imagined to happen in the case of this spring virtually occurs whenever any elastic body is caused to vibrate,—be that body a solid mass, a string in a state of tension, or an elastic fluid. When a bell tolls, for instance, each molecule of it is passing to and fro, between two such positions as e, e' ; and the important law holds here also, as indeed in every other case, that under the same circumstances, the vibrations are isochronous.—It will be convenient that we observe also in this place, how each vibration of an external body, be it what it may, must originate

or create an undulation in the surrounding air, which undulation will form itself into a wave, proceeding outwards on all sides from the place of that primary vibration. Suppose, for instance, that P is the vibrating molecule—that is to say, a molecule alternately advancing and receding; and for the sake of simplicity, let us liken it to a piston, moving in the long open tube $T T'$, through the space $P s$, and again backwards to P . (The linear dimensions of the piston must be considered as very small in relation to the length of the tube.) Had the air within the tube been rigid, the forward motion of P to s would of course have merely forced a corresponding quantity of that air out of the tube at the end T . But the atmosphere being elastic or compressible, the impulse given by the motion of P will compress, in the first place, that portion of it next P . Let

this effect be supposed to have reached A , when the piston stops at s ;—the air formerly occupying the space $P A$ will now be compressed within the smaller space $s A$. The effect of the action of P will just have begun, or rather be on the point of beginning, at the vertical layer or stratum $A Y$, and at the same time it will at the same moment be just ceasing at the vertical stratum at s —the pressure of P then ceasing. The molecules in the vertical strata between s and A will, however, be subject to compression, and in consequence to motion; and near the middle of that line they will be subject to the greatest compression, and therefore to the greatest velocity. Their state may be represented to the eye, if we raise ordinates $X X', Y Y', \&c.$, representing the degrees of compression at $X Y, \&c.$, and connect their extremities by a curve.—Should the piston remain at s , the force accumulated by compression within the space of air $s Y$, will discharge itself on the next layer $A B$, and produce there a state of things exactly resembling its own,—in other words, it will propagate itself onwards, giving rise to a new or second undulation, which in its turn must generate a third, more advanced still; so that the primary disturbance, caused by the advance of P , must result in the creation and propagation of a wave that will advance, as we shall see hereafter, with a definite velocity on all sides through the whole atmosphere. It is easy to see that during the subsistence of the process now described, another—in so far opposite in character—has been occurring on the other side of the piston P . At that place the air occupying a space sensibly equal to $s A$, must have been rarified; and at the close of the second interval this portion will return to rest, while the portion occupying $A' B'$ will come to be in motion. Aerial pulses will thus be produced on every side. Since small

vibrations are *isochronous*, these pulses or waves must also be *isochronous*, and of a length determined by the length of the vibrations of the sonorous body. The pulses in question are commonly named pulses or waves of sound.

2. Seeing, then, that the invariable antecedent of the sensation of sound is a body in a state of vibration, communicating waves or vibrations corresponding to its own to the atmosphere, and thus diffusing its effects, we easily recognize it as the *general* problem of acoustics, to ascertain what special effects belong to the *nature* of the body vibrating; to the *energy* or *force* with which its molecules oscillate; and to the *rapidity* of these oscillations.—(a.) As to the influence of the nature of the body vibrating, no satisfactory physical solution has yet appeared. Two different musical instruments, communicating to the air the same number of vibrations in the same time—each vibration being of equal strength—do indeed affect us with sensations very different. Who does not recognize the difference, for instance, between a note of a flute and the same note of equal loudness produced by the violin? And yet in all known physical attributes the serial oscillations originating in the action of these instruments correspond to a nicety. The full solution of the difficulty may depend on physiology; nevertheless, there must be some decisive physical cause antecedent to the difference of effect on the sensorium.—(b.) The energy or *amplitude* of the primary impulse or vibration, or the contrary, exercises an influence that is intelligible enough. It is clear that this *amplitude* has nothing to do with *rapidity*:—the main-spring of our first illustration, for instance, might have been made to deviate much farther from *A* *s* than *A* *e* is, in which case the sweep or amplitude of its oscillations would have been larger, although *their number in a given time would not have been augmented*. Now, on this amplitude, that attribute of a sound which we term its *loudness*, depends. A note of a chamber organ differs, in this respect alone, from the same note rolled out in York Minster, or by the organ in St. Paul's.—(c.) There remains the question as to the *rapidity of vibration*,—a question of profoundest interest, one concerning which physics can do but a part, for we soon enter the region of physiological psychology. It is on this primary physical element that the characteristic depends which induces us to divide sounds into *grave* and *acute*. The *first* thing that strikes one when entering on this curious subject is the immense compass of the human ear, or rather of our sense of hearing. Savart's experiments demonstrate that sounds are audible, although so extremely *grave*, that they originate in vibrations, seven or eight of which only, occupy a second of time; while, on the other hand, by the same surprising faculty, we can detect the acute note proceeding from a vibrating body giving forth twenty-four thousand waves in the same small portion of

time. Despretz has recently gone much farther,—he thinks we can detect vibrations so rapid, that no fewer than 86,850 are executed in a second. The rapidity of vibrations like these is indeed infinitesimal, if compared with that of the undulations which seem to give rise to the phenomena of vision. At the same time the compass of the eye is small compared with that of the ear: the extremes in the former case being in the proportion of 458 to 727, while in that of the latter they are, to take the most unfavourable statement, as one to *three thousand*. And yet who shall say that our human ear recognizes all possible or even all existing sounds? Multitudes innumerable of the voices of this unfathomed universe may pass us, never to be heard;—our portion of it, in so far as sense is concerned, is probably that of the creature of an hour—not much greater than what belongs to the *Ephemeron*.—Passing, however, from the contemplation of *limits*, let us ask next whether sounds produced within those limits are susceptible of satisfactory classification, or can be supposed to be rationally connected with each other? The reason or ground of the classification now to be explained undoubtedly belongs to the necessities of the human sensorium, or to demands made by the constitution of our perceptive faculty: an analysis of those grounds, and the discussion of their finer relations, constitutes the Science of Music. The physical laws or characteristics of the subject may be simply, as well as very briefly explained.—(1.) A compass of vibrations, in which any velocity or rapidity is taken as the starting point, and which includes all vibrations up to those having a rapidity double that of this initial or fundamental one, is called an *octave*. There is of course no limit to the number of octaves, ascending and descending, except the foregoing limits of audibility. But their construction, or their comparability, in the musical language of different nations or composers, must evidently depend on an agreement as to a diapason or fundamental note. Singularly enough, this has not hitherto been a thoroughly settled point. Savart found that the fundamental *la* springs from 440 complete vibrations in a second; but we find that the actual *la*'s of the grand opera of Paris, of the Italian theatre, and of the theatre of Berlin, originate respectively in 433, 434, and 441 vibrations. Accurate science may thus correct and aid even the highest aesthetics,—*Mundum regunt numeri!*—(2.) All sounds issuing from vibrations, whose rapidity is related according to the natural numbers 1, 2, 3, 4, &c., are termed *harmonic* sounds; in other words, they may be sounded together inoffensively, and even pleasingly. Savart considers that he discerned a physical reason for this. When a cord is set in vibration it appears that, besides the fundamental sound, all the sounds corresponding to these numbers are audible at the same time; that is to say, mingling with the full vibration

of the cord, there are separate and secondary vibrations round the various points in which the cord would be cut, were we to divide it into two, three, and four parts successively. The figure below will illustrate this condition of complex vibration for the ratios 1, 2, and 3.—(3.) The

octave is divided, however, into other intervals, and these divisions constitute what is termed the *gamut*. These divisions technically are—

ut, re, mi, fa, sol, la, si, ut,
1, $\frac{2}{3}$, $\frac{3}{4}$, $\frac{4}{5}$, $\frac{5}{6}$, $\frac{6}{7}$, $\frac{7}{8}$, 2,

—the numbers in the second line indicating the vibrations of each note that occur in the same time. The same intervals belong to every octave—referring them to the primary ut; that is to say, if the primary ut of an octave be 4 instead of 1, each of the foregoing numbers or ratios must be multiplied by 4. There is another gamut used in music for special objects—called the *minor gamut*; its intervals are—

ut, re, mi b, fa, sol, la b, si b, ut,
1, $\frac{8}{9}$, $\frac{7}{8}$, $\frac{6}{7}$, $\frac{5}{6}$, $\frac{4}{5}$, $\frac{3}{4}$, 2,

Also written in gamut minor, are sad and depressed, and are easily distinguished from music belonging to gamut major.—Why the ear will

recognize no sounds produced by other sets of vibrations, as musical, the Science of Acoustics cannot explain, nor does it attempt it. Its concern is not with the subjective influences of vibrations, but with the material antecedents of these remarkable issues.

3. Phenomena so singular, depending on the number of the oscillations executed by the molecules of a vibrating body in a given time, it is clearly of much consequence that these velocities become susceptible of exact measurement. And we shall soon discern that other problems, also of great importance, depend for their solution on our minute acquaintance with the character of such vibrations. Fortunately, modern experimental science has furnished many delicate expedients by whose aid even changes thus evanescent, are rendered palpable alike to eye and ear, and so thoroughly fixed, that they can be subjected to a rigorous evaluation. We shall describe a few of these ingenious and effective procedures.—Perhaps the most interesting, and that which promises the most varied results, is the method originating with Chladni, and extensively employed by Savart, while investigating the vibrations of plates or rods. While such are vibrating, motion seems very unequally distributed among their particles. Strewing fine sand over the vibrating surface, Savart found that it accumulated over spots and lines, which he termed nodal spots and lines,—it being clear that there could be no vibration there. The following diagrams show these lines of repose, as manifested under varying circumstances:—

Experiments of this kind require much care, in order that they succeed. Savart suspended the plate lightly by a clasp of wood at one of its edges; and he caused it to vibrate, not by striking it, but by bringing quite near it another body already in definite and known vibration. The same process may be applied to a bell or glass. Nearly fill a glass with mercury or water; set it then in vibration, and the surface of the mercury or water will indicate nodal lines, as well as the character symmetrical or otherwise, of the rays of sound. At present, of course, we

merely indicate the means of ascertaining the existence and distribution of such nodal lines.—In the second place, a method has to be mentioned, recently proposed by M. Lietaux—the exhibition of the curious and rather brilliant results of which has recently attracted much notice in Paris. It is at once simple and ingenious. Suppose a mirror attached to one of the prongs of a common tuning fork, and that a ray of light is made to fall somewhat obliquely on that mirror, it is clear that the direction of the reflected ray will alter with every vibration of

the fork, should it be made to vibrate. If now this reflected ray be made to strike on a screen, the vibrations of the fork will become visible in the rapid motions of a point of light upon that screen. By aid of this very simple contrivance, M. Lissajoux has been able to render the vibratory movement of solid bodies distinctly visible; to manifest the optical composition of vibratory motions taking place in the same direction; to compound two vibratory motions at right angles to each other; to manifest the accordance of two diapasons separated by any musical interval whatsoever; and to offer the easy means of fixing on a constant or invariable fundamental sound. The applications of this method are indeed most numerous: its radical fault is, that it does not provide or leave any abiding trace of its indications.—The *third* class of instruments to which we shall refer are of a different, and, in so far as the attainment of their object is concerned, of a yet more perfect kind. That object is to measure the exact number of vibrations taking place in a second, that are required for the production of the various musical sounds. *First*, we have the *vibroscope* of Marloye,—the rudest, perhaps, of all. But it acts simply;—it consists in arrangements which permit a point at the end of a vibrating rod to impress marks on a rotating cylinder, whose surface is coated with lamp-black. *Secondly*, we have Savart's plan by toothed wheels. He impresses what vibrations he pleases on a thin plate, by causing it to be struck by the teeth of a wheel moving at any given velocity. The number of strokes per second is the measure of the vibrations, whose sounds or notes are heard. *Last*, and unquestionably the most perfect of all, is the *Sirène* of Cagniard la Tour. This exquisite instrument is described under article SIREN, q. v.

II. THE PROPAGATION OF SOUND.

The previous section has merely established certain very general principles, as the foundation of the Science of Sound. The first special question that occurs is probably this,—With what comparative velocities are these waves of sound propagated through space by the different vibrating substances? For instance, take a rod of iron of 100 feet in length, and a tube of the same length, filled with air; communicate to the end of each the same vibration, or, what is the same thing, let the ends of both be in contact, when a vibrating motion is communicated to either,—by which of the two will that vibration be first conveyed to its other extremity; what will be the difference of time, and on what physical element does that difference depend? It is unquestionable that every vibrating body in contact with another must communicate to it a system of waves isochronous with its own; but the velocity of the advancement of these waves through space, must depend on some physical character of the body to which the vibration is communicated.

—Let us briefly look at this important subject, as it is presented by Experiment and by Theory. (1.) The atmosphere being the main agent in the propagation or diffusion of all sounds with which we generally come into contact, the velocity with which they pass through it, became quite early a matter of anxious investigation. The important fact was soon discovered that, speaking generally, sounds of all *notes*, grave or acute, pass through strata of air with sensibly equal speed: the degree of completeness with which they are transmitted varies with the variation of ordinary circumstances, but not—sensibly at least—the speed of transmission. Probably the most exact definite determination of this velocity, as yet effected, is owing to the experiments made between Montchery and Villejuif, in 1822, under care of the *Bureau des Longitudes*, at Paris. Good experiments of the same sort have been repeated by Moll of Utrecht; and the result is, that through a bed of air of the temperature of 82° Fahrenheit—air of course virtually dry—a wave of sound travels at the rate of 1090·2 feet in one second of time. Now that telegraphic communication is so exact and extended, experiments of this description might be repeated under very favourable circumstances. The velocity of propagation varies even in the case of different elastic fluids or gases. The following numbers may be depended on within small limits of error:—In the vapour of alcohol, the velocity of propagation is 480·8 feet per second; for the vapour of fluoride of silicium, we have 555; vapour of sulphuric ether, 590·1; vapour of chlorohydric ether, 656·2; sulphurous acid gas, 697·5; cyanogen, 757·6; protoxide of azot, 845·6; carbonic acid gas, 846·6; sulphohydric acid, 953; olefiant gas, 1051; bioxide of azot, 1071·7; air, 1090, &c., &c. These velocities become still more varied when we scrutinize corresponding phenomena in the case of liquids and metals or rocks. According to Collodon and Sturm, sound is propagated through water four and a-half times more rapidly than through air; and M. Masson has recently informed us that the transmitting quality of the different metals is represented by the following numbers,—the velocity in air, or 1090·2 feet per second, being taken as unity:—pure lead, 8·976; pure gold, 6·27; cadmium, 7·55; silver, 7·96; platina, 8·41; palladium, 9·81; zinc, 11·14; copper, 11·52; cobalt, 14·25; steel, 14·88; nickel, 14·98; iron, 15·11; aluminium, 15·875. The phenomena involved in these varying velocities of the transmission of the waves of sound are illustrated on the grandest scale on the occurrence of a submarine shock, giving rise to an earthquake. First of all, the wave of sound propagated through the solid rocks reaches and terrifies the dwellers on the neighbouring shores of the ocean; after an interval, a sound reaches them through the sea, along with its terrible waves; and at the close of the convulsion the agitated atmosphere bears its evidence of the vio-

lance that has occurred.—(2.) Turning to *Theory* in quest of a satisfactory, or at least a probable explanation of such varieties, we meet with a few formulæ, which—regarded merely as general theorems—are of very great importance, and nearly circumscribe the subject.—(a.) In the case of solid bodies, Laplace long ago established the formula—

$$v = \sqrt{\frac{g}{e}}$$

where v , the velocity of sound, g , the intensity of gravity, and e , the elongation undergone by a wire or rod of the solid a *mètre* in length, when stretched by a weight equal to its own weight. The *Mechanical Theory of Heat* establishes another form of the relation, viz :—

$$v = \sqrt{\frac{gjc}{2d}}$$

where j is the mechanical equivalent of heat, d , the coefficient of linear dilatation, and c , the specific heat of the body.—(b.) In the case of fluids, whether they be liquids or gases, supposing that the temperature of each particle remains the same during the transmission of sound—we have—

$$v = \sqrt{\left(g \cdot \frac{dP}{d \cdot V}\right)}$$

where P is the pressure and V the volume. This is the formula reached by Newton: but it gave a velocity smaller than the actual velocity by one-sixth of the latter. Laplace detected the error, and corrected the formula. It is this—

$$v = \sqrt{\left(g \cdot \frac{dP}{d \cdot V} \cdot k\right)}$$

k being the ratio $\frac{K_p}{K_v}$, or that of specific heat

at constant pressure and specific heat at constant volume. The action of heat during the propagation of the pulse or wave is the cause of the difference,—necessitating the introduction of the ratio k . Laplace concluded that the formula applied to gases only; it is applicable, however, to all fluids.—It is singular enough, while Laplace's investigations all rest on the old static doctrine of caloric, that notwithstanding the admitted incapacity of that doctrine, their results exactly correspond with consequences flowing from the modern Vortical Theory. (See Art. *HEAT*, § 17.) A sufficiently striking illustration of the caution which should precede our acceptance of physical hypotheses, on the mere ground that certain of their results correspond with actual phenomena.

III. THE NATURE AND EFFECTS OF SPECIAL DESCRIPTIONS OF VIBRATIONS.

We shall now treat briefly of the different kinds of vibrations, and refer subsequently to certain peculiar modes of producing vibrations and musical sounds.

I. The known kinds of vibration are three,—transverse vibrations, longitudinal vibrations, and vibrations originating in the torsion or twisting of a rod.

1. The best and most palpable illustration of *transversal* vibrations is the case of a stretched cord, like the string of a violin, a piano, or a harp. If the string, when in tension, is pulled sideways out of its place, it instantly starts back, through effect of its elasticity, and a vibration commences in a transversal direction, or in a direction perpendicular to the length of the string. Any elastic body may be made to vibrate in this manner. The tuning-fork vibrates transversely, and so do those plates whose nodal lines have already been referred to. The vibrations of a bell are transversal likewise.—(a.) The theory of such vibrations, in the case of musical cords—which, indeed, forms the whole physical theory of a large class of musical instruments—may be said to be complete. One part of it is summed up in the following theorem:—“*The number of the vibrations of a stretched cord in a given time is proportional; 1st, inversely to the length of the cord; 2d, inversely to its diameter; 3d, inversely to the square root of the tension; 4th, inversely to the square root of the density.*” If diameter, tension, and density, remain the same, *the number of vibrations will be inversely as the length of the cord.* It is easy to find from this theorem the precise character of the cords that will yield the various musical notes; but as tension plays so large a part in conferring this quality, the adjustment of the cord is usually entrusted to the hand and the ear. During the vibration of a cord, another very singular phenomenon is manifested, which greatly increases the richness of the sound issuing from it. The cord sends out not only its fundamental note, but *the whole or many of its harmonics, along with it.* An experiment, imagined by Sauveur, furnishes the solution of the puzzle. At a point in a musical string—say one-third of its length from one end—place the moveable stop, and press the string down upon it very gently with the finger. By a stroke of the bow set the third-part into vibration; it will be found that the other part of the string vibrates also—not as a whole, but as consisting of two parts, and exactly as if by another moveable stop the whole string had been subdivided into three parts. Withdraw the stop, and to these three partial vibrations a vibration of the whole string will be superadded. Sauveur concludes that a musical cord does not, when struck, merely vibrate along its entire length, but that each of its halves, each of its third-parts, each of its fourths, vibrates also; and that there-

fore the fundamental note is necessarily accompanied by its harmonics.—(b.) Of the transversal vibrations of plates little is known, save the existence of those nodal lines. No satisfactory theory has been offered in account of them. We may probably soon learn interesting facts from the process of M. Lissajoux. Savart employed these vibrations in investigations concerning the structure of various bodies, such as pieces of wood, crystals, &c. It is clear that variations or irregularities of elasticity may thus be easily detected.

2. *Longitudinal* vibrations are executed in the direction of the length of the vibrating body. The molecules of cords, rods, &c., may, by due precautions, be made to vibrate in this way, and to produce sound. M. Marloye has even constructed a musical instrument on this principle, in which twenty rods so vibrating, give out separate notes. But the chief and, indeed, only important illustration of it, is the case of wind instruments, in which columns of air, enclosed in tubes, vibrate and produce rich musical sounds. It is the longitudinal vibration of the air within the tube of the flute or the pipe of the organ, that evolves their sweet and imposing harmonies. The phenomena of these vibrations were satisfactorily investigated long ago by Daniel Bernouilli. We have no space for the interesting analysis of this eminent geometer, and must be satisfied with a simple enunciation of the laws he discovered. They are six in number:—*First*. All cylindrical or prismatic tubes *of the same length* give out the same notes, if (all being open or all closed at the end opposite the end where the impulse is communicated) their length is ten or twelve times their diameter, and the material of which they are made is sensibly rigid. The *quality* of the sound and its *intensity* vary slightly with the nature of the substance of the tube.—*Secondly*. If a *closed* sonorous tube is made to sound by being blown into with greater or less force, it will give out different notes; and if its fundamental note, or the gravest note it can give, be represented by unity, the other notes will rigorously and undeviatingly follow the series of odd numbers, 3, 5, 7, &c.—*Thirdly*. An *open* tube will also give out different sounds, according to the force with which one blows into it; but these notes are represented by 1 (the fundamental note), and the entire series of natural numbers, 2, 3, 4, &c.—*Fourthly*. The fundamental note of a *closed* tube, and that of an *open* one of the same length, are always in octave. The note of the closed tube being the grave one (1), and the note of the open tube the acute one (2).—*Fifthly*. When an open tube gives the sound 2, one may effect an opening in its middle, and even take away half of it, without its note experiencing any change: so likewise if it gives the note 3, openings may be made, dividing the tube into three parts. These phenomena forcibly recall Sauveur's experiments on the division of

vibrating cords.—*Sixthly*. Between each of the portions into which a sonorous tube may be divided without change of note, there is a thin motionless *slice* or *stratum* of air—called a *node of vibration*. The existence of these nodal strata can be easily proved. For instance, within a shut tube that gives out the second note, a piston may be placed at the first third of its length, without at all altering the note. But were the piston placed anywhere else, the note would not remain unchanged.—Such the leading phenomena of musical wind instruments.

3. Vibrations of *torsion* are probably often produced, but they have not been turned to use. It is needful to recognize them, however, as a phenomenon in molecular physics. Their existence and musical effect may be manifested as follows:—Fix a cylindrical rod at one end, hold it in the hand at some other point, and rub it gently with a bow in a direction perpendicular to its axis. The contact of the hand prevents all *transverse* vibrations, so that the friction of the bow must cause a torsion, giving rise to synchronous vibrations perpendicular to its length. The sound produced is much graver than what would be due to any longitudinal vibration; so that being neither transverse nor longitudinal, the molecular oscillation produced must be circular, or due to torsion.

Although the modes of vibration now described are quite separate and distinct, it is not probable that any actual body ever vibrates purely according to one single mode. They who are conversant with the more modern progress of the Undulatory Theory of Light, will recollect how much of the completeness of that theory is now owing to the recognition of the co-existence of different kinds of vibrations. A phenomenon that sorely puzzled Savart, viz., the existence of inexplicable nodal lines in bars, apparently vibrating only longitudinally, has just been traced by M. Terquem to the co-existence of transversal vibrations. It is the most difficult duty of the artist who constructs musical instruments to provide against such interferences; but the task is lightened by the tendency of all neighbouring vibrating movements (especially if some one of them is greatly superior in intensity) to throw themselves into harmony.

II. As a close to this article, we shall refer briefly to two peculiar classes of phenomena—recently attracting considerable notice—by which musical sounds are produced.

1. The fact that on the contact of bodies of different temperatures musical tones are evolved, seems to have been noticed by Schwartz so long as 1805, and afterwards, in the same year, by Professor Gilbert of Berlin; but the subject did not receive continued or systematic attention until the year 1829. In that year Mr. Arthur Trevelyan happened to be engaged, in the course of some inquiries, in spreading pitch with a hot trowel, or plastering iron. The iron being too hot,

he laid it slantingly against a block of lead, when, to his great surprise, it emitted a shrill note, compared by him to the chanter of the small Northumbrian pipes. Inspecting the iron narrowly, he found it in a state of rapid vibration. It was early established by Trevelyan, Reid, and other experimenters, that almost any of the metals will produce musical vibrations, if a bar of it be laid upon a block of lead or tin—the bar being heated, and the block cold; or if a cold bar of lead or tin be laid upon a hot block of these metals. The explanation, however, was not so easy, and remained until recently a matter of doubt. Professor Forbes of Edinburgh, ever awake to new discoveries, gave the whole subject an elaborate, although not an exhaustive examination; and on the ground of what he considered a number of general laws, he felt obliged to refer the curious phenomena to “a new species of mechanical agency in heat.” There is no need, however, of any new species of agency. Sir John Leslie very early suggested the true and simple explanation. Faraday afterwards confirmed it; and in 1854 Dr. Tyndall, with the sagacity that so largely belongs to him, conducted a series of researches that leave nothing further to be accomplished. It is clear that when the hot body first touches the cold one, the cold mass will expand, and throw off the hot mass; the latter will then descend or fall back: the process must immediately be repeated; and a succession of taps will ensue, rapid and powerful enough to evolve musical sounds. The superior efficacy of lead or tin in this case, was ascribed by Faraday to its great expansibility, combined with its feeble power of conduction. If the explanation be correct, the phenomenon must be an unlimited one—certainly not confined within the limits of Professor Forbes’s laws. His first law was this—“*These vibrations never occur between substances of the same nature.*” But Dr. Tyndall has shown that iron will vibrate on iron, copper on copper, brass on brass, silver on silver, tin on tin, &c., &c. Again, Professor Forbes asserted that “*both substances must be metallic.*”—Dr. Tyndall proves that the production of the tones depends not on the substance of the recker, but, as Faraday’s view would lead us to expect, on its powers of conduction. For instance, silver, copper, and brass, placed on the natural edge of prisms of rock crystal, fluor spar, or rock salt, gave clear, and, in some cases, very precise tones. No fewer than twenty non-metallic substances were examined by Professor Tyndall, and distinct vibrations always obtained. Lastly, Forbes asserts that “*The vibrations take place with an intensity proportional (within certain limits) to the different conducting powers of the metals for heat,—the metal having the least conducting power being necessarily the coldest.*” The overthrow of the first law carries with it the overthrow of this one; for between two pieces of the same metal there can be no difference of con-

ductive power; but Tyndall further shows that it is incorrect in every particular. The theory of Leslie and Faraday therefore stands.

2. The other class of sounds are produced by those curious singing tubes. It has long been known that if an open tube of some length be so held over a jet of burning hydrogen that the flame shall just be within the tube, a musical note is produced, or the tube begins to *sing*. Various explanations were early proposed; but here also Faraday first reached the truth. He refers the sounds to successive explosions produced by the periodic combination of the atmospheric oxygen with the issuing jet of hydrogen gas. Dr. Tyndall has again brought his originality and exactness to confirm and illustrate this explanation. He has shown further, the dependence of the pitch of the note produced, on the size of the flame. The note given out is, indeed, the fundamental note of the tube, or rather one somewhat higher, in consequence of the increased temperature of the vibrating air; but the size of the flame must be such as to enable it to explode in unison either with the fundamental pulses of the tube, or with the pulses of its harmonic divisions. The remarkable part of his paper, however, is its way of manifesting the keen sympathy between these flames and the human voice, or any neighbouring musical instrument sounding the requisite note. “I placed,” says Professor Tyndall “a *sirène* near the flame. The latter was burning tranquilly within its tube. Ascending gradually from the lowest notes of the instrument, at the moment when the sound of the *sirène* reached the pitch of the tube which surrounded the gas flame, the latter suddenly stretched itself, and commenced its song, which continued indefinitely after the *sirène* had ceased to sound.”—The facts have also been noticed by M. Schaffgotsch. See also articles EAR, ECHO, HARMONICS, HEARING, SIREN, SOUND, TARTINIS BEATS, &c.

Actinism. The remarkable phenomena brought out by *photography*, have shown the existence of solar influence due neither to the Rays which produce Heat nor those which produce Light. This third class of Rays has been named the *Actinic* Rays; and the force in question *Actinism*, or Ray-power. The relation of the Actinic, to the other Rays, in the *spectrum*, or as they are separable by virtue of their different refrangibilities, is exhibited by the diagram in next page, taken from Hunt’s *Treatise on Photography*.

From A to B in the diagram is the Newtonian spectrum; recent discoveries extend the coloured spectrum, as distinctly visible, much farther. The curves, C, D, and E, represent the relations of the forces of *Heat*, *Light*, and *Actinism*. The Actinic or chemical rays, are at their *maximum*, in that part of the spectrum where the illuminating power is the least, and *vice versa*; but there appears a second or subsidiary Actinic maximum within the

ACT

heating rays at F. A complete account and analysis of the solar beam, will be found under the articles REFRACTION and SPECTRUM:

x, Actinism, or chemical radiant power. *c*, Light. *n*, Heat.

suffice it to remark in the meantime, that this Actinic Force is almost inversely as the illuminating power: not only do the most luminous rays contain no Actinism, but they tend to prevent chemical change;—an inorganic body exposed to the yellow Ray, resists the influence of Actinic Rays likewise thrown upon it. The reality of this antagonism very distinctly appears in the relation of different climates, hours of the day, &c., to the processes of Photography. The difficulty of obtaining pictures by action of the sun, increases as we approach the equatorial regions; they are more easily obtained in spring than in midsummer, and in the morning than at noon. It would seem also that the Actinic force undergoes modifications, and is subject to cycles, probably not less important than those which are the subjects of Photometry and Thermometry: the cause of such changes, however, has not yet been ascertained. The Actinic Rays have evidently closest relations with the progress of vegetation; to them also is due, the phenomenon of Phosphorescence; and they quicken Electric action.

Actinograph, Dynactinometer, Photographometer. Names given to instruments devised for measuring and recording the variations of the Actinic or Chemical force of the solar ray. Several forms of these are described in *Hunt's Treatise on Photography*. A classical instrument of this kind, of easy use in observation, is still a desideratum.

Actinometer. The temperature of the earth

AUT

or of any point above its surface, reckoned by the thermometer, is not a correct measure of the heat sent by the Sun. Much of the latter heat is not transmitted, but absorbed by our Atmosphere; and the Atmosphere becomes in this way a heating source, the intensity of which is indicated by the Thermometer as we generally employ it. To detect the true quantity of heat emanating from the Sun, we must find how much has been absorbed by the Atmosphere, and if possible ascertain what would be the elevation of temperature, could our aerial envelope be for the moment destroyed. The results of this inquiry are stated under *arts. SUN and RADIATION*: the instruments used in the inquiry are termed **ACTINOMETERS, HELIO-THERMOMETERS, and PYRHELIOMETERS**. The first instrument of the kind was devised by De Saussure: one, similar in principle, but of great delicacy in action, was proposed by Sir John Herschel. We select, however, the instrument called by Pouillet the *direct Pyrheliometer*, for description in this place. Its chief part is a vessel of silver, *A B*, with thin sides, blackened on its upper face so that its absorbing power be a maximum, and containing about 1500 grains in wt. of water. This apparatus is adjusted so that the direct rays of the sun strike upon it. A thermometer, *a b*, whose stem, passing into *c d*, the support of the silver vessel, is thus protected from solar action—indicates variations of temperature.

To insure that *A B* be perpendicular to the incident rays, a corresponding disc is placed below it, and the instrument is adjusted when the shadow of *A B* exactly falls on the disc *A' B'*:—An observation with this Actinometer is made as follows:—The water having attained the temperature of the surrounding air, the apparatus is kept in the shade very near the place where the trial is to be effected:—it is placed so that it receive the full heating action of the sky, without any direct solar rays falling on it; and, during four minutes, a record is kept from minute to minute of its cooling or heating. During the next or fifth minute, it must be adjusted behind a screen so that if the screen were removed, it would receive the direct rays perpendicularly: at the end of the minute the screen should be suddenly removed. Then during five minutes the process of heating must be observed from minute to minute. At the end of the fifth minute replace the screen; restore the apparatus to its former position; and once again observe the cooling, from minute to minute, during other four minutes. The ele-

vation of temperature, t , due to five minutes of direct solar action, will then be

$$t = c + \frac{c + c'}{2}$$

c being the whole elevation of the temperature of the apparatus during the four minutes of its exposure to the sun, and c and c' the cooling observed during the first two sets of four minutes which preceded, and followed the exposure. The theory of the treatment is evident. Pouillet has also proposed an actinometer or pyrheliometer with a lens. It consists of a lens of two feet focal length, at whose focus is a silver vessel containing about 9000 grains in wt. of water, a thermometer being within the water. The shape of the vessel and the disposition of the lens are such, that for any altitude of the sun, the rays can be made to fall perpendicularly alike on the lens, and on the face of the vessel in its focus. The experiment in this case is made precisely as in the former: but the use of the instrument with the lens is preferable during winds. It will appear from this description, that observation with the Actinometer or Pyrheliometer is still of the nature of an experiment; neither so direct nor so easy as observation with the Thermometer or Barometer.

Action, the Least, Principle of. The advance of all Sciences is in this wise. The facts accumulated are grouped at first by partial generalizations, and the difficulties of investigation overcome by partial methods,—methods and generalizations gradually rising in power and extension, until they lead, as their term, to the fundamental law connecting all the facts, and offering a method for the treatment of every possible problem. The history of *Rational Mechanics*—especially of its main department, *Dynamics*—exhibits throughout, such phases. As its exigencies multiplied, they were classed; and partial methods became discerned, capable of application to each class. These methods were termed *principles*, and were often attempted to be established on distinct, and even *a priori* grounds—sometimes on considerations connected with *Final Causes*:—they are, in reality, only Theorems of greater or less generality, which can now be readily deduced from that more extended and grasping conception of the subject of Rational Mechanics, which we mainly owe to D'Alembert and La Grange. The more important of these are known under the appellations of "*The Conservation of Living Forces* (*visum vivarum*);" "*The Conservation of the Movement of the Centre of Gravity*;" "*The Conservation of Areas*;" and "*The Principle of the Least Action*." The character of the first three is explained under the heads *Force*, *Centre*, and *Areas*: it is with the last one alone, that we have at present to deal. The history of the principle of Least Action is curious and instructive. It had been noticed by Ptolemy, that a ray of light passing by reflection from one point to another, adopts the shortest possible course—a

truth flowing directly from the fact that the angle of reflection is always equal to the angle of incidence. On the discovery of the Law of Refraction by Snell, and its promulgation by Des Cartes, the French geometer Fermat—to whom we owe an important step towards the discovery of the Differential Calculus—ascertained that a similar result might seem indicated by that law of refraction; viz.: that while the two media through which the ray passes continue the same, the *sine* of the angle of *Incidence* has a constant ratio to the *sine* of the angle of *Refraction*. Assuming that the ray moves more swiftly through a rare medium than through a dense one, Fermat asserted that in order to pass in the *shortest time* from a point in a rare medium to a point within a dense one, the ray must move in a *broken line*, continuing as long as possible within the rare medium; and his analysis enabled him to discover that the permanency of the ratio of the sines made the *Time* a minimum. Incited by these two singular facts, the imagination of Maupertuis led him to the abstract conception, that Nature must ever act with a view to the *highest Economy of Forces*; and the advanced state of Mechanics taught him to translate this metaphysical notion into the important theorem known by the foregoing name, viz.; that the course of a body subjected to the action of any set of forces is necessarily such, that the integral of the product of the velocity of the body by the element of the curve shall be a *minimum*. Long and angry controversy ensued: geometers finally discarding the *a priori* reasonings of Maupertuis, but accepting his principle as a remarkable and useful truth, capable of being demonstrated by inferior and legitimate mechanical Theorems. The property was further generalized, defined, and properly rectified by La Grange, who showed, moreover, that the so-called *Economy of Force*, is merely an accidental and partial concomitant of the true Theorem—sometimes having reference to the *space* described—sometimes to the *time* occupied, and often predicable of neither. The analytical expression as laid down by Maupertuis, and completed by La Grange, need not indeed be a *minimum*. It is only true that its *Variation* is always 0; so that, for aught we know, the integral may be a *maximum*. The name, therefore, of the *Principle of Least Action*, should be allowed to follow the abstract reasonings of Maupertuis; and in this instance, as in all similar ones, nothing invalidates the dictum of Lord Bacon, that Final Causes are like *Vestals*—not legitimately productive.

Adhesion. The force which unites two substances placed in mutual contact, is called the *adhesive force*. It differs from *cohesion*, which acts only between the constituent molecules of the same body. Its power is measured by the weight which is required to separate the adhering substances. A striking illustration of the power of adhesion will be obtained, if we press together

ÆOL

two pieces of lead, having similar surfaces, well scraped. A very considerable weight will be required to separate them. If, instead of merely placing two bodies together, we make the one slide for a few seconds rapidly over the surface of the other, the adhesion will be stronger. The air between the substances is partially, in that way, expelled. If we could expel all the air between two bodies, we should have a pressure of 15 lbs. per square inch of the surfaces, parallel and equal to the adhering surface, keeping the bodies together (atmospheric pressure). Several artificial compositions have been manufactured in order to produce a permanent union between two bodies. Generally, these bodies are of the same kind, and the composition is so made as not readily to break up itself, and at the same time to adhere strongly to each. Marine glue is probably the most powerful of these preparations. When a substance is dipped into any liquid, a film of the liquid generally adheres to it. This shows that adhesion obtains between solids and liquids. The phenomena of capillarity are partly explicable in the same way. Adhesion is also to some extent produced, when one body is forced into the mass of another. Its difference from *cohesion* (*q. v.*) is perhaps rather hypothetical than real.

Æolian Harp. A musical instrument by which sounds are produced, when a current of air passes over the strings. It was first constructed by Kircher, who gives a full description of it in his *Musurgia Universalis*, (9. 852.) The following method of construction is not exactly his; though very nearly approaching it. It is found to give more distinct tones than are produced by his method. Make a box of thin deal, equal in length to a window in which it is to be placed, about 4 or 5 inches deep, and 5 or 6 wide. Glue on it, at the extremities of the top, two pieces of wainscot about half-an-inch high, and a quarter of an inch thick, to serve as bridges for the strings; and within side, at each end, glue two pieces of beech about an inch square, equal in length to the width of the box. Into one of these bridges fix as many pegs as there are to be strings, and into the other fasten as many brass pins. String the instrument then, fixing them by the pegs and the pins respectively, and tune the strings into unison. The strings must not be drawn very tight. Place the instrument then, in the sill of a window where there is a brisk current, and we shall have all the notes of the diatonic scale commingling together, sometimes in the most exquisite harmonies. The explanation of the Æolian harp is easily found in that part of the article on Acoustics, which refers to the vibration of cords, and which gives an account of the different notes which intermingle in the case of any one vibrating cord. (See *ACOUSTICS*). Vide *Young's Inquiry into the principal Phenomena of Sounds*.

Æoliopile. Æoli Pila. The ball of Æolus. An instrument first mentioned by Vitruvius (1. 6).

AER

It consists of a ball of metal, to which a pipe is attached by a screw. The ball is filled with water, and heat is applied, when steam issues from the neck with considerable force. The instrument was employed to illustrate the origin of winds. It is only now interesting from its having been the first recorded instrument where anything was made to depend upon the motive power of steam.

Aerolites or Meteoric Stones. The extraordinary meteors to which the *Aerolites* belong are distinguished into three classes. 1. *Falling Stars* or *Shooting Stars*; 2. *Globes of Fire*, or *Bolides*; and 3, *Aerolites* proper, or those solid masses that fall to the surface of the earth through the air. The complete discussion of the questions stirred by this remarkable subject, we shall give under the article *METEOR*: in this place we propose simply to explain the distinctive character of *Aerolites*.—After much pardonable incredulity, the fact is now accepted that stones and mineral masses do fall to the Earth through the atmosphere. The general unbelief was overcome by the systematic inquiries and report of Biot, undertaken by desire of the French Academy regarding the shower of *Aerolites* that fell near l'Aigle in Normandy, on 26th April, 1808. A list of all recorded phenomena of this description was afterwards drawn up by Chladni, to whom we owe our earliest systematic knowledge of the singular subject. Chladni's catalogue is necessarily very imperfect, and does little more than establish the fact, that the phenomenon cannot be called a rare one. Most of these occurrences must be unrecorded: for instance, when the stones fall into the Ocean, or when they have fallen unnoticed, as must have been the case with the large mass discovered by Pallas in Siberia, and with other such masses, as travellers have found at the Cape of Good Hope, in Mexico, Peru, or Baffin's Bay, &c., But within recent years we have had several falls substantiated, as matter of fact—as clearly as in the case of the *Aerolites* of l'Aigle. On the 1st of October, 1857, about 4.45 o'clock in the afternoon, Baron Seguer was, with some workmen, in an avenue of his chateau of Haute-feuille, near Charry, in the department of Yonne. They were suddenly startled by several successive detonations in the air, quite unlike thunder, and by marked atmospheric agitations: on returning to his house, the Baron found that glass had been broken. He learned immediately that a shower of *Aerolites* had fallen at the same moment a few leagues from Haute-feuille, in the commune of Des-Ormes. Hastening to the spot, he found that a mason working at the time on a scaffold had witnessed the fall, and been nearly struck by one of the *Aerolites*, which buried itself several inches in the earth at the foot of his ladder. Seguer presented this stone to the Academy of Sciences; and stated that a proprietor of Chateau-Renard had seen at the same hour a globe of fire passing rapidly through the air towards Verulson—in the

precis direction of the locality where the Aerolites fell. The stone in all respects resembled those of Aigle;—the important and really novel part of the phenomenon was, however, the identification of the fall, with the *Bolide* seen at Chateau-Renaud.—On the 9th of December, 1868, a similar event occurred at Clarac, in the canton of Montrejean, in the Haute-Garonne. The people were first attracted by a sudden and alarming explosion; and at the same moment the air was filled with millions of sparks, followed by a shower of ashes. A very large stone fell near the church, striking the farm-house of the widow Jeanne-Marie Caperan. This stone was so hot as to burn the hand. It resisted fracture at first, but the peasants succeeded ultimately in breaking it up. Another and still larger fragment was afterwards found at d'Aussun. It had penetrated the earth nearly four feet, making a hole upwards of a foot in diameter. The mass weighed about 100 lbs. avoirdupois. This stone was also broken up by the peasantry; but the Abbé Froment, professor of the seminary of Pognan, who assisted at the extraction of the Aerolite, secured a large fragment of it. It wholly resembles the fragment of the Aerolite of Clarac, now in possession of the Curé of that place.—The nature of these masses has been determined by chemical analysis. They contain the following elements:—Oxygen, Hydrogen, Sulphur, Phosphorus, Carbon, Silica, Chromium, Potassium, Sodium, Calcium, Magnesium, Aluminium, Iron, Magnetic Nickel, Copper and Tin. The following are the chief types in which these elements are found combined:—1. *Metallic Iron*, containing small quantities of Nickel, Cobalt, Magnesium, Manganese, Tin, Copper, Sulphur, and Carbon.—2. *Sulphuret of Iron*.—3. *Magnetic Iron*.—4. *Olivine*.—5. *Silicates* and other earthy substances.—6. *Chromate of Lime* in small quantities.—7. *Oxide of Tin*.—The Aerolite of Montrejean was carefully analysed, and gave, a magnetic substance—Iron or Nickel; Sulphuret of Iron; Peridot, Labrador; Hornblende, &c. One remarkable circumstance remains to be noticed. An Aerolite fell about 10 o'clock in the evening, near Kaba-Debreczin, on 15th April, 1857; and in this M. Wöhler has found a small quantity of ORGANIC MATTER, akin to paraffin:—a fact wholly unexpected, and going far to establish the planetary character of these singular masses.—As to the origin of such Meteors, three hypotheses have been proposed. First, That they are of atmospheric origin like rain or hail;—meteors formed by aggregation.—Secondly, Laplace thought that they might be projected from volcanoes in the Moon. Thirdly, Chladni and others believe them small Planes, or fragments of Planets moving through space, which on entering our atmosphere, lose their velocities and fall to the earth. The first hypothesis is untenable. The second, in the form given it by Laplace, equally so.—We shall re-

turn to these speculations under the more general article METEORS: but it seems fitting to subjoin here the leading conclusions recently arrived at by Reichenbach, after an analysis of facts probably the most complete hitherto made. (See *Poggendorf Annalen* for December, 1858). The following are Reichenbach's chief propositions:—(1). Twelve Meteorites or Aerolites, at least, fall on the earth daily, or, 4,500 every year.—(2). Many of them are small; others of great size, some as large as a horse, others of the size of a house, and a small hill. He suspects that some of our large masses of dolerite have had a meteoric origin.—(3). The composition of these masses closely resembles that of the volcanic or plutonic rocks of the earth;—the substances entering into their composition belong without exception also to the composition of our Planet.—(4). The mean specific gravity of these Aerolites is rigorously equal to that of the Earth; so that on every side there seems a relationship between these two formations. With rather a stretch of fancy, Reichenbach asks, may not our Earth itself be a mass of Aerolites?—(5). The satellites of our Solar System, the Asteroids, and the large or primary Planets, have similar relations as the Aerolites: their respective magnitudes, weights, &c., do not differ more, than Aerolites do with one another.—The point to which Reichenbach's speculations converge is this;—all our planetary bodies—including the Earth, have had what in one sense may be termed a meteoric origin; i. e., *these Aerolites are simply small Planets; and, as such, are constituent and essential parts of our System.* We descend from the larger Planets to small Aerolites gradually and consecutively. These occupy, indeed, a middle space between the Asteroids and the Comets. Reichenbach had previously attempted to show that Aerolites are merely Comets that have passed, by condensation, from a mass of *impalpable dust* to a solid state;—a supposition which accounts well in so far as Comets are concerned, for facts so puzzling as their transparency, their inability to refract light, the polarization of their light, and the circumstance that the light they emit is reflected solar light: in a word, the theory is, that a Comet is merely a swarm of solid grains or molecules far from each other, exceedingly light, transparent, luminous by reflexion, perfectly mobile, and floating through empty space. But an analysis of his own superb collection of a hundred and forty Aerolites showed Reichenbach further, that they consist for the most part of very small spheres or spherules, united by an amorphous substance; or what is nearly the same thing, that they are aggregates of millions of spherules, at one time probably existing *freely* and apart in space. If then, previous to this aggregation or condensation, such a *swarm* had a motion of translation, what could it be except a cometary mass?—It is certainly neither our wish nor our function to pronounce dogmatically on

AER

speculations so closely connected with the obscurest portions of cosmogony; but, in this case, they will not improbably succeed in fulfilling one primary object of all such hypotheses, viz.: they may stir inquiry, and strengthen the belief that even the most strange anomalies are all subject to Law.

Aeronautics. The history of aeronautics commences at a very early period. Archytas, the famous philosopher of Tarentum, constructed a dove able to maintain itself in the air, and Aulus Gellius mentions that this result was accomplished by enclosing in its body an air lighter than the atmosphere. Roger Bacon, about the beginning of the 14th century, attempted the construction of a machine which should give man the power of sustaining himself in the air, and of directing his motions while in it. Cavendish in England, and Lichtenberg and Pickel in Germany, experimented also upon vessels filled with hydrogen. These attempts were made in the laboratory, however, and came to no practical result. Joseph Montgolfier was the first who made an aerial voyage. His attention was excited by observing that a paper bag, which he had thrown on the fire by chance, mouth downwards, rose up in the air. He repeated the experiment, and always with the same success, and the idea occurred to him of raising a balloon by filling it with heated air in the same way as the paper bag was raised. He put his idea into execution at Avignon, in 1782, and more publicly at Annonay, June 5, 1783, in presence of the states-general. Pilatre des Boziers and the Marquis d'Arlande were the first to trust themselves to the balloon, and to risk a voyage in the air. They passed over the city of Paris in their voyage. This, as it was the first, was also the last voyage with balloons filled with heated air. The weight of the fuel to be taken up was considerable, and the danger of the flame dilating in the upper layers of the atmosphere, where the pressure is smaller than at the surface, was very great. In fact, the balloon of the two voyagers caught fire, and they narrowly escaped death. Besides, a rapid descent while the fuel was unexhausted might be very dangerous to buildings of all sorts. Still further, the ascent depended upon the lightness of heated air, and if the air were heated much above the boiling point of water, the balloon would be apt to burn. In consequence of these disadvantages, the Montgolfiers (so called from their inventor) were abandoned. But M. Charles, about this time, repeated the experiments of Cavendish regarding vessels filled with hydrogen gas, and carried them into practice. MM. Charles and Robert rose (December 1, 1784) from the garden of the Tuilleries. The gas, from some imperfection in the balloon, beginning to leak out, they descended; Robert left the balloon, and Charles alone reascended; and rose about five times as high as Pilatre des Boziers. This experiment was decisive. Since then very many balloon

AIR

ascents have been made. None are more celebrated than that of MM. Biot and Gay Lussac, from the important scientific information regarding the state of the upper regions of the atmosphere which it gave. M. Gay Lussac, in a second ascent alone, rose to a height of about 23,000 feet. The barometer stood at a trifle less than half its height at the surface of the earth ($\frac{2}{3}$ being the exact fraction). The temperature also was very considerably changed. When he commenced to ascend, his thermometer stood at 66°·74 Fahr., and at the greatest elevation it had fallen to 14°·9 Fahr. This fall was experienced in the course of a few minutes.—The aeronaut usually takes with him several bags to serve as ballast, and in order that, by throwing himself clear of them, he may as rapidly as possible rise to a higher elevation. It is necessary for him to be especially careful not to fill the balloon too full of the gas. In that case, when the pressure round the sides becomes less, as it does in the upper air, there is a violent tendency to explosion. The balloon is usually provided with a stop-cock, by which the gas can be let off in case of such danger. All the materials of the balloon should be tried before they are used, with a view to ascertain their capacity of resistance. The form of balloons depends very much on the purposes for which they are intended—whether for rising, or moving about horizontally in the air, or wandering about at the will of the wind. The power of directing a balloon is still a desideratum. Perhaps a very close study of the common structure of fishes, and of the manner in which they direct their motions of ascent or descent, and horizontal motion, might reveal something of the true answer to this problem; just as the consideration of the structure of the eye suggested to Euler the possibility of achromatism. One practical direction is, that the aeronaut should first rise above the region of currents, where, if he can succeed in obtaining a very small directive force, he will reach his end. Balloons, with metallic plates, instead of the ordinary silk or taffetas covering, have been constructed. They were safer than any others, it was thought, against breakage by the distention of air. It has been found practically, that, in consequence of our not being able to procure them homogeneous, they are exposed to far more numerous chances of rupture than the ordinary balloons. The balloon has been employed to enable military men to observe the operations of an enemy; but it is found not well suited for this. The only really practical purpose to which it has yet been turned, is that of enabling us to arrive at such a notion of the state of the upper regions of the Atmosphere, as we could not otherwise attain.

Air Engine. In the manufacture of engines for our great public works, and for our extensive travelling requirements, there are several very important desiderata, the nearer the approximation to which becomes, the more valuable our

engines must be considered. Thus, every engine requires to be provided with safeguards, so that the carelessness of attendants may produce the least possible damage either to the engine itself, or to the building in which it is placed, and the people who may require to be near it. Safety-valves are usually provided, so that when the steam in the boiler has reached, in any way, so high a pressure as even to approximate to danger of explosion, a free passage may be provided for it into the external air. Then, again, it is necessary that an engine should be moderately light in many cases. In stationary buildings this is not so necessary; as the driving engine may usually be placed on the ground, and so may be of any weight. Even, then, however, the important consideration of economy would suggest that there be no unnecessary masses of material employed in its construction. Where, on the other hand, the engine is to be put in a steam-boat, or used on a railway, this consideration becomes of the utmost importance. In such cases the moving force resident in the engines, has to drag the weight of the engine itself along, and thus wastes its capabilities in mere reflexive action. Thus, if a locomotive can be constructed 30 tons in weight, to do the same work as one of 40, besides the important diminution of first cost, the latter engine will, after all, be able to drag a much smaller train, since it has 10 tons to haul behind it, in addition to its proper load, more than the other. A consideration of still greater importance in the construction of a good engine is its economy of fuel. The cost of an engine we have already seen to be of the very utmost importance, but it would be mistaken economy which would make a machine of less capability, or more likely to go wrong, serve in place of a good though expensive one. The first outlay is once for all. But if with two different engines the same effect can be produced, by the consumption of less fuel in the one case than in the other, a permanent advantage is on the side of the former. There is a great daily difference in the expense of "feed," and as, before long, in a large engine, that expense comes to be greater than that of the machine itself, it is better to have one which will consume less fuel for the same work, even although heavier and more expensive. In steam-boat and locomotive engines this is eminently so. The same considerations of expense hold here as before, with the additional important consideration, the lightness of the invariable load. The locomotive engine has always a tender attached, with the coals and water which it carries. If two engines can be wrought to the same extent, doing the same work, the one carrying five tons of coal for its journey, and the other ten, it will be clear that the first can carry precisely five tons additional of extra load. Part of the power of an engine is always wasted in moving its own machinery, and in carrying the load of fuel which its machinery requires. The

more these are economized, the more has the engine to spare for its proper work. In a steam-boat this is especially note-worthy. A steamer consuming some 20 tons of coal per day (one of very moderate size would do more), must, for a whole day, drag about this load, losing 20 tons of freight by it. If she has, moreover, to pass across a sea, where she cannot get supplies readily, she has to take in coal for her voyage, perhaps 500 tons, and as at her starting she must haul this with her, she loses a large amount of freight. If, still further, she have a longer passage to perform, one of perhaps 70 days, as to Australia, her load of fuel for the journey may become more than she is able to carry, even without any freight. She must, therefore, carry perhaps only one-third of it, losing so much as one-third of her capacity for freight, and requiring to turn in, probably much out of her way, twice for a fresh supply. Frequently there is no place on the route where a good supply of fuel can be immediately obtained, and even when there is, the time spent in taking it in, is a serious drawback to our employment of the resources of steam engines on long voyages.

A multitude of similar desiderata might be pointed out in the steam engine: meanwhile we content ourselves with these three. A good engine must be at once safe, light, and economical in its consumption of fuel.

Taking, then, these as the requirements, engineers and mechanics have thought of very many ingenious processes by which they might be satisfied. The physical philosopher, considering the whole character and procedure of a perfect engine,—wasting no heat in its operations, not heating its containing vessels, losing none by their variations, nor dissipating it in smoke or waste steam; in fact, doing everything which an engine that operates by converting heat into power (*a thermo dynamic engine*) can do, tells mechanics how far they can proceed. Having reached a certain point, they must stop. Contrivances of theirs may bring us nearer and nearer to that point, may make us almost arrive at it, but there is a limit beyond which these cannot lead us. (See Professor Thomson's paper on the *Mechanical Action of Heat*. Royal Society of Edinburgh *Transactions*, vol. xx.)

Given the temperature of the body by which heat is communicated, and the temperature at which the used-up material is sent off, the physicist can tell what proportion of the whole value of heat is used in work, and what proportion must be lost in a perfect engine.

We can here allude only very briefly to the convertibility of heat and work—referring for a more extended account of it to the article HEAT. When we lift a body weighing one pound through one vertical foot from its position, we put forth a certain definite effort, or do so much work (in this case, what is called a unit of work). When we put our hand out so as to catch a body mov-

AIR

ing in any direction, we also put forth an effort, or do so much work. This effort of ours has been put forth to counteract the inertia of the body by which it would be forced to go constantly on in the same direction at the same rate. The body in its motion, therefore, is said to put forth effort to do work also, and that precisely equivalent to the effort required to stop it, or the work done in so doing. Now, according to the mechanical theory of heat, every heated body is one whose particles are in motion, more or less violent, among themselves. Each particle, therefore, is doing a certain amount of work; and, adding all the work of all the particles, we get a sum of work done by the whole heated body.

Now, when we have such a body, it may be possible, by certain contrivances, such as the Steam Engine, to reduce the particles of matter either to rest, or to a much slower motion, by transferring their motion to new masses of matter. Thus, when a bullet shot off, strikes upon any object not fixed steadfastly, the bullet retains part of its motion, and transfers part of it, to the new object. In this case, the *whole* measureable motion lost by the bullet, is not transferred to the moveable mass, but a considerable part of it goes instead, to the *production of internal heat motion*, in the mass of the bullet and of the body struck. Motion, therefore—*visible motion*—is here converted into *heat*. So, conversely, perceptible heat can be converted into visible motion; as in the steam engine the consumption of coal gives rise to the motion of the machine. An exact equivalence, capable of easy statement, holds between these heat motions, and ordinary motions. The amount of heat necessary to raise the temperature of one pound of water one Fahrenheit degree from 82°, is called the thermal unit, and this thermal unit is accompanied by thermal motions, which do as much work, as is done in raising 772 pounds of any matter one foot vertically from the ground.

The mechanical philosopher comes now to the engineer; and finding how much coal his engine requires, knowing the mechanical equivalent of a pound of coal—the amount of work done by the particles of its mass moving among themselves, when it is heated—he tells him what would be the total work obtainable from it, if this work could all be converted into a palpable mechanical form. Finding next the temperature to which he raises his steam, and the temperature at which the condenser is kept, he tells him how great a proportion of the whole equivalent of the fuel expended, will be realized by a perfect engine working at these temperatures.

The law is expressed as follows:—

$$W = J \cdot H \cdot \frac{s - T}{\frac{1}{E} + s}, \text{ where } w \text{ is the actual work}$$

done; H the number of units of heat; and J the equivalent in units of work, of one unit of heat.

AIR

s and T are the temperatures in centigrade degrees of the source of the steam issuing into the cylinder, and of the condenser respectively.

Hence, $\frac{s - T}{s + \frac{1}{E}}$, a fraction smaller than 1, will give

the proportion sought. Now, T , the temperature of the condenser, must be kept in given circumstances pretty nearly the same, and $\frac{1}{E}$ is constant

($\frac{1}{E} = 273.224$ by experiment). T is constant,

because the condenser, kept constantly plunged in cold water, which is changed as quickly as it becomes heated by the emitted steam, does not permit the temperature to rise much or rapidly. The only change, therefore, in the value of these proportions will arise from the change of value in s . Let us see how this will effect the results, for a perfect engine:—

$$\frac{s - T}{\frac{1}{E} + s} = 1 - \frac{T + \frac{1}{E}}{s + \frac{1}{E}}$$

Here everything is constant but the one quantity

s . As it increases $\frac{1}{E} + s$ increases, and

$T + \frac{1}{E}$ decreases; therefore, $1 - \frac{T + \frac{1}{E}}{\frac{1}{E} + s}$ increases

with the increase of s . If s become very great indeed, sensibly the whole possible mechanical equivalent may be obtained. If it be very small, the realized proportion will become very small along with it.

From which, it appears that the increase of the temperature of the steam admitted into the cylinder secures an increase in that *duty* (as it is called) of a perfect engine, which converts heat into work.

We must, therefore, necessarily, when we wish economy of fuel, work with engines having the steam admitted into them at very high temperatures. But here we are met by a practical limit. If we use steam at high temperatures, we cannot get rid of its enormous expansive power; in consequence, probably, of the great amount of heat which it takes into its mass and retains as latent; which heat while increasing the expansion, does not raise the temperature. With high-pressure engines, we must construct, therefore, very strong boilers, and with such boilers we shall never be quite safe from innumerable accidents; while the expense will be vastly increased. We must have the pressures not so very high above atmospheric, as steam at even 150° centigrade (302° Fah.) would give us; while, at the same time, the temperature at this pressure shall be very much greater than 150°. With such a temperature, which is not by any

AIR

seems low for a steam engine, we should have the proportion $\frac{s - T}{\frac{1}{2} + s} = \frac{1}{2}$ nearly, T being con-

sidered $= 50^\circ$ centigrade, or 122° Fah. A temperature, at all events, not far below 50° , will certainly obtain for T ; the condenser becoming always somewhat heated by the admission of the heated material from the cylinder. From Southern's experiments (*Philosophical Magazine*, 1847, part I.), we find that the pressure of steam at 302° Fah. would be above $4\frac{1}{2}$ atmospheric; and, this pressure from the inside, only a very carefully constructed boiler could usually sustain (the excess over the internal atmospheric pressure being above 50 lbs. per square inch); while the least derangement of construction would be productive of very dangerous explosions.

We have here then a want—that the temperature of the heated mass—the source—be raised as high as possible; and a difficulty,—that if we raise it to any height above 300° Fahrenheit degrees, we shall meet with practical difficulties of the most alarming kind. These are, moreover, inseparable from the use of steam.

This circumstance has urged the attention of mechanicians to heated air as a moving power. The advantage of employing it,—should mechanical difficulties of construction be surmounted,—will be at once evident from this fact, that the same pressure at which steam has a temperature about 300° Fah., gives a temperature about 1700° Fah. to heated air.

The most recent investigations on which reliance can be placed, are contained in a paper read by Mr. Joule of Manchester, before the Royal Society (*Philosophical Transactions of the Royal Society*, 1852, vol. i.), to which, for a fuller treatment of the subject, we refer. We proceed to detail the principal steps of his process, and the results at which he has arrived.

He considers the Air Engine, in its simplest possible form; supposing that all such practical difficulties as the loss of heat by radiation from the heated air vessels, &c., are got over. His theoretical Air Engine is an apparatus consisting of two separate cylinders, each communicating by valves with a receiver.

In one of these cylinders a volume of air is compressed, increasing, equally therefore, in

AIR

temperature and in pressure, since the apparatus loses no heat to the surrounding air. Suppose the process to have gone on for some time, the receiver being opened, its valve opening inwards, communicating with the condensing cylinder, being driven in at each successive descent, and then shut by the pressure of the air just admitted, when the piston of this condensing cylinder is drawn up. A valve in this piston, also pressed inwards, admits common air when it has been drawn up, and shuts again, when a new compression commences. Suppose, then, the receiver filled with air above the ordinary temperature and pressure (heat being all this time applied to the receiver). We shall have this confined air opening a valve which goes outward from the receiver, and entering beneath the piston of an expanding cylinder driving it up. Now, there is a certain amount of air driven in, compressing the air in the condensing cylinder. When an equal amount of air has been given off with the receiver, the valve opening into that cylinder shuts. This is managed by an arrangement of the weight of the valve. The air in the receiver, so expanding as it does when this valve is open, gets more room, and presses less upon any vessel enclosing it. Then as the valve is made somewhat heavy, it shuts by its own gravity—the moment that the air has lost the elastic force which counterbalanced this gravity and drove the valve open.

At this point there is no material advantage gained, upon the whole. The ascending piston might be made, through that part of its ascent which it has now performed, to do the same work nearly that was required to push down the descending one. The air, however, at this time, in the expanding cylinder, is still hotter, and presses more powerfully on the sides consequently, than common air. The piston is accordingly still pushed upwards, and may, in doing so, be made to work an engine. By another valve, when this operation has been carried far enough, the piston is allowed to resume its original place, and to be again pushed up by a new rush of air from the cylinder.

The process employed in Mr. Joule's experiments is this:—The receiver is filled with air at atmospheric density, which is heated to a moderately high temperature (890° – 464° Fahr.) At this temperature the air in the receiver, being kept in constant volume, presses against the sides of the receiver with considerable force (25·95 lbs. per square inch). When the piston, which has to descend through 12 inches, has passed through a part of its stroke (4 inches), the pressure is the same as that of the air in the receiver. The air is, however, at a much lower temperature (107° – 81° Fahr.), because it is not kept at constant volume, but compressed. The valve then opens into the receiver. During this part of the process, the air had opposed a continually increasing resistance to the downward motion.

AIR

During the remainder of the descent, if the receiver be pretty large compared with the cylinder, it will remain what it is at the end of this. The fact of the whole body of air contained in the cylinder and in the receiver being compressed into one space may be disregarded if it be so. The heat then applied to the air in the receiver increases its temperature and its volume, and drives open the valve, and makes the second piston ascend. Here, also, the fact of the air contained in the receiver expanding through part of the cylinder until the original work spent be regained, can be considered as producing no material change upon the pressure. When the valve closes at the moment it is completed, and the communication between the cylinder and the receiver is closed, the air in the *cylinder* alone expands, and is reduced to the atmospheric pressure.

In order to show how the calculation can be effected upon which depends the excellence of such an air engine, we will quote an example given by Mr. Joule. For the mathematical principles upon which his calculations are founded, we must refer to his paper.

He has a condensing cylinder 12 inches long, and with a sectional area of one square inch. The area of the section of the exhausting cylinder is the same. He commences with air of the density of the atmosphere in the receiver, having a temperature of $890^{\circ}\cdot464$ Fahr. According to the gaseous laws, the pressure at this temperature will be (supposing that of atmospheric air to be 15 lbs. per square inch,) $25\cdot95104$ lbs. per square inch. The piston will require to be wrought through one-third of its stroke (4 inches) before the air reaches this pressure. At this point the temperature will be $107^{\circ}\cdot3094$, and the work which will have to be done would be sufficient to drive $6\cdot587154$ lbs. through one foot of space. The atmosphere, however, has operated upon the square inch of area of the piston, with a force of 15 lbs. through 4 inches of space. There is, therefore, due to it force sufficient to drive 5 lbs. through 1 foot. Hence the effective work done by the engine, absorbed in this part of the process, is $1\cdot587154$. During the remainder of the stroke, there is a pressure of $25\cdot95104$ lbs., acting on a square inch through $\frac{2}{3}$ ths of a foot, and of this pressure 15 lbs. acting similarly is balanced by the atmospheric pressure. We have, therefore, $\frac{2}{3}$ ($25\cdot95104 - 15$) = $7\cdot300693$ foot lbs. as the amount of work done in this part of the process by the engine. In the expanding cylinder, again, as the process goes on, until as much air has been let out as came into the cylinder, we have, in that part of it where there is emission from the receiver, a passage of air through 12 inches, with a pressure of $25\cdot95104$ lbs. resisted by an atmospheric pressure of 15 lbs., and giving off thus $10\cdot95104$ ft. lbs. of work. The communication being now cut off, the air expands until

AIR

it reaches the pressure 15 lbs. As it was required to compress the volume of air in the condensing cylinder to two-thirds of its original bulk, in order to increase the pressure from 15 to $25\cdot95104$, it will be necessary, inversely, to expand it to three halves of its bulk, in order to bring it from the latter pressure to the former. The air will accordingly expand after the communication has been cut off, through 6 inches, and the effective work will clearly be $\frac{2}{3}$ ($1\cdot587154$) = $2\cdot305781$. Hence the work given off, in the whole course of the operations, will be $10\cdot95104 + 2\cdot305781 - 7\cdot300698 - 1\cdot587154 = 4\cdot418924$ ft. lbs.

Now, in order to find whether the engine be economical, we must consider what has been expended to attain this result. The only source of expenditure is, then, the heat required to raise the temperature ($107^{\circ}\cdot3094$ Fahr.) of the eight cubic inches of air, at the constant pressure already stated, up to $890^{\circ}\cdot464$. We find, then, that the heat required to do so would raise 1 lb. of water $0^{\circ}\cdot048043$ Fahr., and, therefore, dividing $4\cdot418924$ by this, we obtain the number of ft. lbs. of work obtained from every amount of heat capable of raising 1 lb. of water 1° Fahr. In this case we shall have $102\cdot66276$ ft. lbs.

But, the theoretical maximum, when all the heat employed is made full use of, and none of it wasted (as in this case the air is let off from the exhausting cylinder, at $287^{\circ}\cdot5$ Fahr.), is 772 ft. lbs. for every amount of heat capable of raising 1 lb. of water from 0° to 1° Fahr. In a perfect steam engine (free, as we imagine this engine to be, from all loss of heat by radiation to the surrounding bodies, or conduction through the vessels composing it), where steam at 284° Fahr. is employed, which is about as high as it can safely be used at, 209 ft. lbs. of the 772 may be thus brought up, or converted into work.

If, however, we keep the temperature and pressure of the air in the receiver very much higher than what we have supposed, we shall obtain more favourable results. Thus, if we have a pressure of $70\cdot60445$ in the receiver, the piston would require to pass through 8 inches of its stroke in order that this may be reached. If the air be, further, of double the ordinary density, its temperature will be $706^{\circ}\cdot559$, that of the air forced into the pump will be at the same pressure, and with temperature $311^{\circ}\cdot3732$. The temperature of the air escaping into the atmosphere will be $277^{\circ}\cdot5$, and the amount of work obtained will be $279\cdot9628$. None of these temperatures or pressures are such that they could not be borne by well-constructed vessels.

Considerable practical difficulties, however, stand in the way, but the results already attained warrant a confident hope that air engines may yet be brought into favourable competition with steam engines, and may perhaps supersede them.

Mr. Joule suggests the following remarks to

AIR

those who may be desirous of constructing a good air engine :—

The receiver need not be much larger than either cylinder. In the practical engine, the exhausting valve opens just as the valve opens from the receiver to the condensing cylinder. Hence the volume is kept sensibly equal to that in the receiver originally, and the pressure, therefore, is sensibly the same. A coil of pipe might form the most convenient receiver, as having a constant heat most readily applied to it, so as to maintain the air within at a uniform temperature. If this be secured, the air engine would act regularly.

The ordinary methods, described more fully in the article on the STEAM ENGINE, would require to be adopted in order to transfer the work from the cylinder and piston rod to the weights to be moved, and in order to secure the opening of the two valves, as just described, simultaneously.

Air Gun. An instrument in which the elastic force of compressed air is made use of as the moving power. We give a representation of a section of the common air gun in that figure below. There

are two cavities in the gun. The one is closed at both ends, by a plate and a moveable piston, and opening into the other by a valve, which is moved by the trigger, and which is placed immediately behind the bullet, *k*, in the open barrel. The piston is so constructed that it can be opened and fresh air supplied, when the air first used has become exhausted. The piston is then pushed upwards, and the air in the barrel is condensed. If the cavity in the stock of the gun be very large compared with the passage beside the barrel, a very high degree of condensation may be obtained by the expenditure of all our strength. The trigger is then touched, and the air entering behind it expands violently, driving the bullet before it. The trigger is then left free, and recoils, closing the valve, and leaving the air somewhat less condensed than before. A considerable number of shots may be discharged, however, with the same air, if the condensation has been very great at first. The velocity which the air gun gives a bullet, depends of course upon the degree of condensation. When the air has been condensed into about $\frac{1}{10}$ th of its bulk, the velocity will be about half that produced by gunpowder. This is, however, a very high degree of condensation. The air gun is too expensive for ordinary use. The least defect in the fitting of the condensing piston, or in the construction of the cylinders, would render it useless. In war, *etc.*, the force which one using it requires to ex-

AIR

pend, is a serious practical objection to its general adoption. It might, perhaps, be readily charged by small steam engines kept constantly working. The invention of it is ascribed to Ctesibius, who lived in Alexandria, B.C. 120. His instrument is described as having discharged arrows by the elastic force of condensed air. Marin, a native of Lisieux, in France, revived the invention in modern times, and presented one to the reigning sovereign, Henry IV. Instead of a simple piston, a condensing syringe is employed practically, which, with much less waste of space, produces greater condensation. See AIR PUMP.

Air Pump, is an instrument for extracting the air from a vessel. We shall explain along with it an instrument for condensing air into a vessel, depending upon the same principles, and called the *condensing syringe*, as the air pump is the *exhausting syringe*. Fig. 1 represents the former, and fig. 2 the latter, instrument. The

Fig. 1.

Fig. 2.

bulb, *O*, in either case, is the vessel, the air of which is to be wrought upon. The valves, *B* and *A*, open upward in fig. 2, and downward in fig. 1. Suppose, then, in fig. 2, the piston raised from the bottom to the top of the tube. As there has been no air in the tube, it rushes through *B* and fills the whole space. It loses, however, in pressure, and is consequently unable to lift the valve, *A*. After it has risen to the top, the valves, *A* and *B*, close. Now, push the piston downwards, the downward pressure upon *B* is increased, but it only opens upward, and the air in the vessel, therefore, is not disturbed during the downward motion of the piston, but remains at the same pressure as the whole air in the machine after the first operation. There is, however, powerful compression of the air in the tube produced in the descent, and when the pressure becomes sufficiently great, the valve, *A*, is lifted and the air escapes. Let us suppose the vessel to be 8 times the size of the tube, and examine what the result of these processes will now be. At the end of the first, the air has expanded to $\frac{8}{9}$ of its original bulk, and so $\frac{1}{9}$ of it is contained in the tube, and $\frac{8}{9}$ in the vessel. At the end of the second process this $\frac{1}{9}$ is expelled, and the $\frac{8}{9}$ remains. When another pair of similar processes were completed, we should have $\frac{8}{9}$ of $\frac{8}{9}$ remaining. After five pairs we should have $\frac{8^5}{9^5}$, or about $\frac{1}{10}$ remaining: and by con-

AIR

tinuing the process we should succeed in reducing the air remaining within to any fraction, however small, of the original quantity. The rapidity of the process will depend, if the workmanship of the instrument be perfect, upon the tube bearing a large proportion to the vessel to be exhausted. One practical difficulty is thus remedied. When the fraction of the original quantity of air left in the tube becomes very small, its pressure has become reduced in the same proportion. In consequence, when we raise the piston from *B* to *A*, the air, having lost its elastic power, comes to be unable to lift the valve, *B*, and no further exhaustion would be possible. In fact, if there were left $\frac{1}{100}$ th of the original, the pressure would be $\frac{1}{100}$ th of 14.7 lbs. per square inch. Suppose the valve, then, to be 8 oz. weight, and 1 square inch in surface, there will be a downward force of 8 oz., besides a slight cohesive and frictional force, opposing an upward force of $\frac{1}{100} \times 16 \text{ oz.} = 2.352 \text{ oz.}$, and the valve would consequently remain at rest. To obviate this, a string passes from the one end of the piston to this valve, so long as to become tightened just before the piston reaches the top, so as to open the valve, however small the upward elastic pressure of the air may be. The condensing syringe works thus:—Let the piston be pushed down. Then, as the air will rush outward, the valve, *A*, will be pushed up, and the whole content of the tube pushed into the vessel. In this state the pressure upon *B*, when it closes, upon the restoring of equilibrium will be, in the case we have supposed, $\frac{1}{100}$ the original pressure, and will, therefore, keep it easily closed against the air. When the piston rises, as there is no air between *A* and *B*, the tube will be refilled with common air. When we push down the piston again the same process will be repeated, but the valve, *A*, will not open until the piston has gone through $\frac{1}{2}$ of its stroke, because then the pressure will be just equal above it and below it. There will be then $\frac{1}{2}$ more pushed in, and the process may be continued as far as we choose. Latterly, the work of pushing the piston down will become very great, and so much the sooner the larger the proportion is which the contents of the tube bears to those of the cylinder. Here the condensation increases arithmetically, $1 + \frac{1}{2} + \frac{1}{2} + \frac{1}{2}$, &c., representing the results of each successive pair of strokes; in the case of the exhausting syringe, the progression is geometrical

We engrave the common air pump. A tube communicates from the bottom of the plate with

($1 \times \frac{1}{2} \times \frac{1}{2} \times \frac{1}{2}$, &c.). The methods by which the practical difficulties of the mechanism are overcome, and by which the instrument is made capable of more extended practical applications, need not be recounted here.

ALG

one or two exhausting syringes, *a* and *d*, the pistons of which are wrought by rack-work, moved by the turning of a handle. Sometimes a barometer is placed inside to serve as a gauge of the degree of exhaustion. Torricelli made the first vacuum, but Otto Guericke first constructed an air pump, which he exhibited publicly at Ratisbon (1654, A.D.). Boyle, Hauksbee, Gravesande, Smeaton, and others, have improved upon his model by adding rack-work, putting two syringes for one, &c. The principle has remained constantly the same

D'Alembert *Principle of*. To the illustrious Frenchman, whose name this principle bears, belongs the unquestioned honour of placing the science of Dynamics on a basis sufficiently broad for all possible requirements. Previous to his time, Dynamical problems were not resolvable by any general method; each class of problems requiring the aid of some special theorem or method applicable to that class alone;—in many cases, indeed, the method had to be found for the particular problem. D'Alembert conferred on Rational Mechanics the inestimable boon of a method applicable to every form of investigation; and, what was more, he practically reduced *Dynamical* problems to mere *Statical* ones. His principle has the further advantage of being easily explained. Suppose a number of bodies connected by a system of forces, it will always be easy to detect the positions that will be occupied by the bodies, at the end of the next moment of time, or the spaces which they will all pass through, during the next moment, supposing the system to continue in action. But it will also be easy to detect the spaces through which they would pass during the same moment, were the *system* or the *connection* suddenly broken up. Compare, then, these two sets of spaces, viz.: the spaces through which they *will* actually pass, and the spaces through which they would pass if *free*. By the theorem of the *composition of forces*, the former spaces may be resolved into the latter spaces, and a third set of spaces. But this third set indicates the motions destroyed because of the *connection* of the bodies, or because they act and react on each other, through a System. And, as action and reaction are always equal within a system; it follows that the sum of the quantities of motion annihilated must be equal to 0; in other words, that what one set of the bodies have gained, another set will have lost. So that we have an Equation of equilibrium, which, rightly treated, will unfold the characteristics of the system of Forces under consideration. La Grange at once recognized the signal value of this Principle of D'Alembert, and made it the basis of his methods in the *Mecanique Analytique*.

Algebra, taken in its full generality, is now the most potent arm of Mathematical Science. As with all great powers, the efficacy and extraordinary grasp of Algebra, were not suspected during its rude beginnings; nor does it seem improbable that its capabilities as a help in the pursuit

of Truth, are as yet but very partially known. As imported from the East by the Pisan Merchant Leonardo, about the year 1200, it was merely a contrivance to save trouble—a sort of short-hand writing, applied to the solution of Arithmetical problems: it has already passed far beyond that, having grown into an instrument by which we can disentangle the most complex relations of Quantity, Form and Force; and determine the effects of their most complex combinations: in future times, it may ascend into an Organ of Universal Logic, and enable us, with an equal power, to disentangle the more subtle processes of Thought. In illustration of the bearing of this latter remark, the student is referred to the recent works of Mr. Boole. Of a subject like Algebra, we can give little account in this Dictionary: it will be enough to advert, under three heads, to the leading phases under which, as an abstract science, it at present appears.

(1.) *Arithmetical Algebra*. This comprehends the whole of the original Algebra, as known to the Hindoos, the Arabs, or to Diophantus Vieta or Cardan. It is simply what Newton called it—*Arithmetica Universalis*; and its artifices are as follows:—to denote the ordinary Arithmetical operations, symbols of operation such as $+$, $-$, \times , \div , $\sqrt{}$, &c., are employed: instead of known or fixed numbers, the Algebraist uses letters, such as a , b , c , &c.; and for quantities really determined, through their relations with others, but whose explicit value has not been actually worked out, he employs the letters x , y , z , &c. The reasoning on which the Arithmetical Algebraist adventures, is of course purely Arithmetical; that is to say, he can admit nothing either in operation or result, which cannot be predicated of pure numbers. His art, however, gives him the immeasurable advantage of reasoning and determining generally, instead of requiring to do so for every special case; general theorems concerning number can thus be formed, and laws laid down for the easy treatment of whole classes of problems. Included within arithmetical algebra, we have the solution of Numerical Equations, the doctrine of Permutations and Combinations, and of Chances, and the Diophantine Analysis in its largest extent:—*q. v.*

(2) *Symbolical Algebra*.—A vast extension of the primary algebra; one whose methods and results were accepted, long before it was felt necessary to revise and reconstruct its logic and foundations. In this—the true modern algebra—the symbols of operation are considered no longer representatives of definite arithmetical processes; they are symbols of operation, defined merely by their relations to each other. For instance, $+$ and $-$ are merely two symbols of inverse operations; \times and \div are also each other's reciprocals, or inverses; while $+$ and \times are connected by a general relation, suggested by the relation between addition and multiplication, and inclusive of it. Viewed from a point of view so abstract, all those

symbols whose occurrence and employment in arithmetical algebras were sources of ever-recurring puzzle and vexation, (such as *negative quantities*, *numbers less than nothing*, and those curious *imaginary quantities*, as they were fitly termed), take on intelligible and important meanings, and become symbols of actual and rational processes. The student will learn much concerning the value of the change now referred to, even in this limited respect, from the second volume of Dr. Peacock's admirable treatise on algebra; nor can it require to be more than hinted, that, under cover of this general idea, other signs of relation—signs, adequate in number and significance, to all possible relations of things and thoughts—may become definite logical signs in an Universal Symbolical Algebra. As to the old symbols or representatives of *number*, these may of course be made representative of any definite thing or idea, known or knowable, through its fixed relations with others. Already algebraic science teems with hints of what its fabric will one day become,—not the least important, being those tendencies towards a pure *Calculus of Operations*, which one easily detects through all its more daring generalizations. The following divisions of what is commonly called algebra, cannot be treated logically, unless on the basis of this extension of the meaning of symbols:—the theory of *indices*, including so-called *imaginary expressions*; the general theory of *equations*; the *arithmetic of sines*; *exponential quantities*; *series* and *development* in general. The entire application of *Algebra* to *Geometry* reposes on an extension of the meaning of the ordinary symbols: something on this subject will be found under QUATERNIONS.

(3.) *Algebra, Double, Triple*.—Terms applied to those important extensions of symbolical algebra, which promise to enable it to cope more directly and easily with problems concerning space of two or three dimensions. For all that we can say on the subject see GEOMETRY SYMBOLICAL. The student is especially referred to a remarkable treatise on *Double Algebra*, by Professor De Morgan.

Algebraic Geometry. See GEOMETRY ANALYTICAL.

Algebra, the Modern. See POLYNOME.

Altitude in Astronomy is the arc of the great circle passing through the zenith, intercepted between the object and the horizon.

Altitude and Azimuth Instrument.—

An instrument that has played an important part in practical astronomy, and which, although superseded to a large extent by the use of Meridional Instruments, has recently been restored to our great Observatories, under several forms, most recently and perhaps most effectually at Greenwich, by the counsel and under the especial care of Mr. Airy. The general character of an altitude and azimuth instrument is this:—*First*, there is a horizontal circle finely divided and

supposed to be planted perfectly horizontally, and so that the zero point of its divisions coincide with the meridian line, or with the exact south. If this circle is not perfectly horizontal, or if the zero point of its divisions does not coincide with the exact south point, the indications of the instrument, in so far as this portion of it is concerned, will be erroneous; but as careful testing can find out that exact amount of error in either particular, which remains after mechanical adjustment has done its utmost, the correction required to be applied to every individual observation may be deduced, and the observation thus rendered as good, as if the instrument had been perfect. From the centre of the horizontal circle an upright pillar arises, which ought to be perfectly perpendicular to the plane of that circle; and to the side of this pillar is attached a vertical circle, to which the telescope belongs, through whose optical axis the observer discovers the star he desires to fix. By the theory of the instrument, this vertical circle, in whatever way it is turned—as the pillar to which it is attached moves round—ought to be perpendicular to the horizontal circle; and the zero point of its division should coincide with the absolutely horizontal or the absolutely just zenith point. These requisitions never being exactly fulfilled by mechanism, corrections must be applied here also; so that the accurate use of the instrument is by no means an easy task. Something further on this subject will be found under CORRECTIONS; and further still under CIRCLE. The importance of the instrument consists in this:—observations can be made by means of it, much oftener than is possible by instruments which are confined to the meridian; a quality of great moment, in the case especially of comets, whose apparition is so evanescent, and which, in uncertain weather cannot be often seen on the meridian. Its inferiority to meridian instruments, is owing to its comparative complicacy; but this has been got over to a marvellous extent by the skill of our famous workmen, as well as by aid of the theory of corrections. The most celebrated Altitude and Azimuth instruments are the great ones by Ramsden; the Westbury Altitude and Azimuth instrument by Troughton; the great vertical Circle of Ertel; and last, and perhaps best of all, the instrument just alluded to, recently erected at Greenwich. Among the many reforms carried out so vigorously by Mr. Airy in the instrumental department of that great Institution, this is not the least: he has attempted in the first place to exhaust all that mechanism can do on behalf of the solidity—the firmness, of astronomical instruments and their adjustments. We shall require to advert to this subject again under CIRCLE; but probably the triumph of the Astronomer Royal has been nowhere more decided than in the case of the instrument now more especially referred to. A sketch of it is subjoined;

fi
s
E
I

ALT

homogeneous mass, i.e. taking no account of its internal irregularities with regard to *heat*, &c., it is easily shown that the densities of these various beds diminish according to a certain definite ratio as we ascend; in fact, in relation to altitudes increasing in *arithmetical* ratio, the densities diminish in a *geometrical* ratio; or, what is the same thing, the several altitudes form a peculiar system of logarithms of which the reciprocals of the densities are the natural numbers, that is—

$$A - \lambda \log \frac{1}{D} = -\lambda \log D$$

$$a = \lambda \log \frac{1}{d} = -\lambda \log d.$$

Whence—

$$A - a = \lambda \log d - \lambda \log D = \lambda \log \frac{d}{D}.$$

Or supposing $a = 0$, and consequently that d is the density of air at the surface of the earth, we have for any altitude—

$$A = \lambda \log \frac{d}{D}.$$

The next question is, what is this peculiar system of logarithms? Or—as any one system of logarithms can be converted into any other system by multiplying the former by a constant quantity—we have to fix a value, m , that will make the following equation true:—

$$A = m \log \frac{d}{D}.$$

The term *log.*, now represents the logarithms of the ordinary tables. This m is detected by experiment. It involves our determining according to what peculiar geometrical ratio the density diminishes with height: and m is found to be very nearly 60,000: therefore—

$$A = 60,000 \times \log \frac{d}{D} \text{ feet.}$$

Or since the heights of the barometer are proportional to the densities of the air, we have, naming these, h and H :—

$$A = 60,000 \times \log \frac{h}{H} \text{ feet}$$

h being the height of the barometer on the surface of the earth, and H the same height at the top of the mountain, or other altitude, which it is desired to measure. Such is the simple basis of the theory at first laid down by Dr. Halley; but it is greatly complicated in practice, by the corrections, requiring to be applied to the foregoing easy formula. These corrections mainly arise, from the influence of variations in heat upon the barometer and the atmosphere; from variations in the force of gravity, depending on the height of the stations, and the latitude of the place; and as has been lately pointed out

ALT

by Bessel, from the modifications produced by the existence of a humid atmosphere of peculiar habitudes, within the dry or permanently elastic one. When all conceivable corrections of this kind are applied, the formula becomes extremely complex—so complex indeed that it cannot be used unless with the aid of subsidiary tables—*hypsometric tables*, as they are called on the continent. Numerous collections of tables of this kind, with directions for use, exist in this country. We only specify those of Mr. Baily and Mr. Galbraith. A copious set were published by Oltmanns, and applied to Humboldt's invaluable observations among the Andes; but on the whole, the best we have recently seen are those by Delcros—taking into account every member of Laplace's minute and comprehensive theoretical formula—published in the *Annuaire Meteorologique*, for 1849, at Paris. None of these tables, however, include Bessel's correction regarding the humidity of the air; a correction whose importance he indicates in No. 856 of the *Astronomische Nachrichten*. In the *Annuaire* above mentioned, for 1852, a new set of tables are produced by M. Plantamour, having reference to *humidity*, and certainly they leave nothing to be desired. It is worth while to estimate, by a testing example on a great scale, the value of this new correction. Calculated on the ground of observation, by MM. Bravais and Martins, on their ascent of Mont Blanc, on 29th August, 1844, the height of that mountain appears by the tables of Delcros to be 4814.5 French metres; calculated by M. Plantamour's tables it is 4811.7 metres; the difference being 2.8 metres, or about 1 in 1600, *one-sixteenth per cent.* The question naturally occurs, whether these minute theoretical corrections, are not far within any possible accuracy of observation? For this subject see *BAROMETER*. In the meantime, for general observations with *ordinary* instruments, we commend the following simple rules. The heights of the mercury and the indications of the attached and detached thermometers being observed at both stations, as nearly as possible simultaneously, put in practice these rules:—
(1.) Correct the length of the mercurial column at the upper station, adding to it the product of its multiplication into twice the difference between the degrees on the attached and detached thermometer—the decimal point being shifted four places to the left. (2.) Subtract the logarithm of this corrected length, from that of the lower column; multiply by six; and move the decimal point four places to the right: the result is the approximate elevation in English feet. (3.) Correct this approximation, by shifting the decimal point three places back, and multiplying by twice the sum of the degrees on the detached and attached thermometers; the product, being added, will give the true elevation.

AMP

Amphitrite. One of the small planets between Mars and Jupiter. See **ASTEROIDS**.

Analysis. Mathematicians understand by *Analysis*—in the widest and most common acceptance of the term—*Algebra*, and all branches of the calculus of Magnitudes by means of *general signs*, in which there is no trace of specialty, or anything that can indicate the particular nature of the Magnitudes. The rules of the Calculus once adjusted to a small number of the fundamental properties of such magnitudes, the Calculus becomes a language—a logical instrument—which works, so to speak, of itself, or without farther attention being necessary than what is required to see that the *rules* be thoroughly obeyed. For instance, *analytical geometry*, after expressing by a preliminary synthesis the characteristic properties of the objects considered, deduces all other properties by the pure force of the Calculus; the special object ceases to occupy the inquirer's thoughts, which are all bestowed on the effort to overcome the difficulties of the Calculus, should there happen to be any. And similarly, *analytical mechanics* is the method of translating into general language the fundamental conditions of equilibrium and movement, so that, after such translation, all else may be deduced by the simple application of the rules of the Calculus. The advantage of analytical methods consists in the generality and regularity of their procedure.

Analytical Geometry. See **GEOMETRY ANALYTICAL**.

Anemometer; now a most important instrument in all meteorological Observatories. The object, as its name imports, is to measure the *wind*—its *direction*, and *force*. The only one in use, until recently, was Lind's, a small instrument, in which the wind blew into the mouth of a tube, always turned towards it by a vane, and depressed—in proportion to its force—a column of liquid therein contained. The defects of such an instrument are obvious. It could not be very sensitive; but above all it wants the essential power of registering its own indications. Mr. Adie of Edinburgh removed this last objection, and, to some extent, the former, in a statical anemometer on something of the same principle as Lind's. We shall here briefly describe the three modern instruments that seem best adapted to the important requisitions of meteorology:—(1.) The first is Dr. Whewell's. By means of a vane, a small windmill is kept turned to the face of the wind; and by its revolutions, it indicates the wind's velocity. The direction of the vane, and the working of this little wind wheel, thus mark the two important elements, viz., the direction of the wind, and its velocity; and the question remained, how these elements and the changes in them could be registered. The swift movements of the wind wheel were, in the first place, made, by an endless screw, to com-

ANE

municate a vertical motion to a pencil working on that screw (which screw was about $2\frac{1}{2}$ feet long) so that the pencil pressing on a sheet of paper marked the length of its progress during any interval of time elapsing between two observations. This was connected with the element of direction in an ingenious way. Through the centre of the instrument a fixed pillar is placed, of about four inches in diameter, and around this pillar a sheet of paper can be temporarily placed, ruled vertically according to the directions; or so that the pencil aforesaid strikes on its north line when the vane indicates north, or its west line when the vane indicates a west wind, and so with other directions. The pencil thus gradually travels down on the outside of this cylinder, marking, on the various direction-lines, the velocities of the wind blowing in these directions; and when it has reached the bottom of the paper, in proportion the instrument must be readjusted by the removal of the pencil to the top of the endless screw, and the application of a fresh sheet to the cylinder. The defect of Whewell's anemometer as a registering instrument is this:—it does not register the element of *time*; it simply gives the integral velocity of the wind in all the directions in which it has blown during the interval between different notices by the observer. Still, although thus limited, its registering is of great consequence; and, as our first self-registering instrument, this anemometer has contributed importantly to the evolution of various phenomena of the winds. (2.) Superior to Dr. Whewell's, at least in one paramount element, is Mr. Osler's anemometer; the instrument still chiefly in use, and which is always receiving modifications at the hands of its ingenious inventor. Mr. Osler, of course obtained the direction of the wind from a vane. The vane communicates, by a long rod, its own motion to a small pinion wheel within the observatory. The pinion, by means of a ratchet, converts this rotatory motion into a linear one, and the ratchet carries a pencil that strikes on a sheet of paper lying below it, and ruled according to the normal directions of N.W.S.E. This sheet of paper does not remain fixed under the pencil, but is gradually carried on by a clock, so that while the pencil oscillates to and fro, as the direction of the wind shifts, these oscillations are found written on the ruled sheet beneath it, in strict connection with the *time* at which the changes took place. The next requisition undertaken to be answered by Mr. Osler, was to register the *force* of the wind. Immediately below the vane, and attached to it,—of course in this way always facing the wind,—he places a brass plate, one square foot in diameter. To the back of this brass plate is attached a spring, of tested strength; a spring beaten back according to the force blowing on the plate. By means of a wire passing through the rod which communicates *direction* to the observing room,

this spring communicates with a counter-spring. As the upper spring is beaten back, the lower or counter spring is free to unfold; and as it unfolds, a pencil, placed above the sheet formerly spoken of, starts out and impresses a mark upon that sheet, whose length thus indicates the force of the wind. The effect of this registering will be better understood by the annexed copy of one of the sheets. The middle tracing is the line of direction for twenty-four hours, and the lower tracing is the indication of the corresponding force. Mr. Oaler has added, by a very simple contrivance, a third pencil, which writes down the quantity of falling rain. This as recorded appears in the third or upper tracing of the annexed sheet.

The instrument we have described is quite a beautiful one, and extremely complete. It gives, we have seen, the direction of the wind, the force of the wind, and the quantity of rain; a separate pencil records each on a sheet which is carried onwards beneath the pencils regularly by a clock. The observer has therefore merely to supply a fresh sheet every twenty-four hours, and to make numerical reductions of these sheets as they are successively taken off. The main defect of Mr. Oaler's anemometer is this:—it does not register with sufficient accuracy light aerial currents; nevertheless, its indications have already thrown much light on the more important relations of the winds. (8.) The last instrument requiring notice here is an anemometer by Dr. Robinson of Armagh, suggested to some extent by the characteristic machinery of Dr. Whewell's, but certainly a

great improvement on its prototype. Dr. Robinson was led to the construction of his anemometer by a rigorous analysis of the imperfections of the previous ones. Mr. Oaler's, it will be observed, registers the pressure and not the velocity of the wind. Now the relative variations of the pressure of the wind are found to be twice as great in any breeze as those of the velocity; so that a pressure-gauge is subject to the most uncertainty. It is laborious also to deduce velocity from pressure; and as velocity is the element we want, a pressure-gauge ought if possible to be avoided. Whewell's gives, or ought to give velocity; it does not give it accurately, owing to the imperfections inhering in a windmill vane. Sir William Snow Harris found that the spaces traversed by the recording pencil are not as the velocity but rather as its square. The external form of Dr. Robinson's anemometer is represented in the annexed sketch:—

The wind vane, *v*, indicates direction, as in all cases, but instead of the windmill vane in Dr. Whewell's instrument, a horizontal arm is placed at *g*, carrying at its extremities cups, whose convex sides are placed opposite to each other, so that the power of the wind to make it turn, resides in its effect on the concave side of the cup, over its effect on the convex side. These hollow hemispheres are in

fact perfect motive agents, substituted for the imperfect windmill vanes; they are perfect, because the motive effect on them is uniform and unchangeable; whereas, the ordinary windmill arms change in their susceptibility with the angle according to which they lie,—indeed not one of them can without actual comparison be interchanged with another. After numerous experiments Dr. Robinson concluded himself warranted in laying it down as a general law, that in a horizontal windmill of this description the centre of the hemispheres move with one-third of the wind's velocity, except in so far as they are retarded by friction. A result of the most important kind, as it guides us for the first time to a mode of DIRECTLY measuring the velocity of the wind. The machinery by which Dr. Robinson proposes to carry out the registry of his results is fully described in vol. xxii, part 8, of the *Transactions of the Royal Irish Academy*. If the principle of his anemometer is unobjectionable, it must be confessed that there is an im-

ANE

perfection in its registries, or power of exhibiting that triple representation of time, velocity, and pressure which so eminently distinguishes Osler's. Meanwhile, meteorology is greatly indebted to the investigations that led its admirable author so far. As to the information concerning aerial currents communicated by anemometers, we refer to the article WINDS.

Aneroid Barometer. See BAROMETER.

Angle. The opening, or the measure of the opening, of lines or planes that meet. This opening, or degree of inclination, of the lines or planes has no relation to the absolute spaces between them; the magnitude of these depending on the lengths of the lines or sides, with which lengths the *angle* has nothing to do.—*Angles* can be compared with each other; one angle being either *equal* to another, or *greater* or *less* than it. Angles also bear to each other the relation of *proportion*. All which, follows from the fact that two angles may be equal to each other, and are so when—the angular point and one side of each coinciding—the other coincides also. Angles, as quantities, are distinguished from lines, as quantities, in this—they have a *natural unit* to which they can all be referred. Lines have no natural unit; there being nothing beyond convenience to induce us to measure a length by *inches, feet, yards, or miles*. But the RIGHT ANGLE is a constant and absolute angular unit; so that angles can always be expressed in pure numbers, representing the proportion they bear to the right angle. Important consequences from this fundamental distinction will be noticed hereafter. (See PARALLEL LINES).—The following are technical definitions of certain kinds of angles very commonly spoken of:—

1. Of plane angles, a *right angle* is that made by a straight line perpendicular to another; strictly defined as one of the two angles which one straight line standing on another makes with it when they are equal. An *obtuse* angle is *greater*, and an *acute* angle *less*, than a right angle.

2. Of solid angles, that contained between two planes (or, which is the same thing, two surfaces, for which planes can be substituted along the straight line of contact) is called a *dihedral* angle. It measures the space between the planes. The angle made by three adjacent planes is *trihedral*; and by many adjacent planes *polyhedral*. The *dihedral* angle reduces to a plane angle. The trihedral and polyhedral are the true solid angles. At the corner of any room a good example of a *trihedral* angle is presented.

3. In astronomy, the *angle of position*—formed by the arcs drawn through a star and the poles of the equator and ecliptic respectively—the arcs along which declination and latitude are respectively measured. *Hour angles*, the angles made by the arc through the poles and a star with the meridian. This changes from hour to hour with the diurnal motion. These are also called *horary*

ANO

angles. *Angle of commutation*, the angle between two lines drawn to the centre of the sun from the earth and the place of any planet, when reduced to the ecliptic. *Angle of elongation*, formed by two lines from the earth, to the sun and a planet respectively. *Angle of longitude*, the angle formed by the meridian and the circle of longitude of a star, the circles cutting at the pole of the ecliptic. *Angle of parallax*, formed by the vertical and the circle of latitude.

4. In optics, the *visual or optical angle*, that formed by two rays from the centre of the eye to the extremities of an object. The image on the retina is proportional in magnitude to this image, and it is by it that the eye estimates *directly* the size of objects. *Angle of incidence*, the angle contained between the direction of a ray, falling on a surface, and the perpendicular to the surface, at the point where it falls on it. *Angle of reflection*, the angle of this perpendicular and the reflected ray. *Angle of refraction*, the angle between its continuation and the refracted ray. *Angle of deviation*, the difference of the angles of incidence and of refraction. *Angle of polarization*, the angle which the reflected polarized ray makes with this perpendicular (the *normal* to the surface at the point).

These are the chief, though far from being the only angles referred to, in a technical way, in the different departments of science.

It has been pointed out above, that the right angle is the natural unit of the angle. However indispensable for ultimate reference, however, the right angle is too large for ordinary use. All angles except one (in the limited acceptance usual to the term) would thus be fractional parts of the unit angle. In consequence, the right angle is divided by us into 90 equal parts, each called a degree; each of these into 60 minutes; each of which is again subdivided into 60 seconds. The introduction of the system of decimal measures into France, caused a proposal to subdivide the right angle into 100 degrees, each into 100 minutes, and each of these into 100 seconds. In some books we find this method, but it has not been generally adopted.

Anion. One of the terms introduced into electrical science by Mr. Faraday; its opposite is *Cation*. By anion is meant that part of the body under decomposition, by or through means of the electric current, which goes to the *anode* side or pole of the current; and by *cation*, the body that goes to the *cathode* side. See next article.

Annular. See ECLIPSE.

Anode. The technical term proposed by Faraday for the side or extremity of the decomposing body, at which the electric current, according to former phraseology, *enters*, in other words the *negative* side. It is the side at which oxygen, chlorine, acids, &c. are evolved. The opposite or positive side—the same author proposes to term the *cathode*—that side at which

ANO

the combustible bodies, metals, alkalies, and bases are evolved. Further on this subject under **ELECTRICITY**.

Anomalistic Year. So called because it depends upon the position of the apogee, to which we refer the anomaly. (See ANOMALY). If the orbit of the earth were a perfect ellipse, the anomalistic year would be exactly equal to the tropical, or common year. (See TROPICAL YEAR). The axis, however, is, as it were, twisted forwards after the moving body in the direction of its motion, so that after it has completed a full revolution, there still remains the space between the old apogee, where it completes it, and the new apogee, which has moved in the direction of the

motion. The apogee moves, in fact, about $11''-8$ in a year, and the moving body has to traverse $360^\circ + 11''-8$ in order to complete a revolution of this sort. The anomalistic year is, therefore, longer than the common year, and is 365 days, 6 hours, 18 minutes, 45 seconds. The figure will illustrate this. After the moving body has gone round from A, the apogee, at the commencement of motion to A, back again, it has completed a tropical or common year. In that time, however, the axis has moved forward, and the apogee has taken a new position at A'. The time occupied in passing from A, round the whole circumference and on to A', is called the anomalistic year.

Anomaly. An angle measuring apparent irregularities in the motions of the planets. They move in ellipses, having the sun in one focus. Let the ellipse $APPM$ represent the orbit of a planet, s being the focus, and P the position of the planet at any given moment. Then the anomaly—what is called the *true anomaly*—is measured by the angle ASP , A being the point of the perihelion, and P the position of the planet. Again, if the planet be supposed to describe its orbit uniformly, passing over equal spaces in equal times, its position would be different from what it really is, because the law of its motion is different, except at the aphelion and the perihelion. Suppose that in the time which it takes to describe the arc AP , A would pass according to this law the arc AZ ; then ASZ is what is called the *mean anomaly*. If again, we describe a circle upon AM as diameter, and draw from P , QPN perpendicular

ANT

to $A M$, joining Q , the point where this line cuts the circle with C , the centre of the circle, the angle $A C Q$, is called the *eccentric anomaly*. When

we speak of the sun or moon, we conceive them both to describe elliptic orbits round the earth, because, although in fact, only the moon does so, yet we refer all motion naturally to the earth as the fixed point in the universe, and, because by considering the earth at rest, we introduce neither fundamental error, nor increase the complexity of calculation. In speaking of a planet's satellites, we conceive the planet itself at rest; and in treating of double stars, the one is supposed to revolve round the other. The mean and eccentric anomalies are thus, in all cases, imaginary angles, originated for facilitating the use of tables.

Antarctic. See ARCTIC.

Anthelia. *Crowns* in meteorology are circles, one or more, around the sun or moon, and concentric with these luminaries. *Anthelia* are phenomena of quite the same kind, but in the part of the sky opposite to the sun; in that particular they are analogous to *rainbows*. They are seen in this wise:—When the sun is just rising, and the observer is between the luminary and a cloud or fog, he observes around the shadow of his head, projected on the cloud or fog, an *aureola*, or glory, whose brightness gradually fades into distance. In the polar regions the phenomenon is always seen where a fog exists while the sun shines; and upon mountains it occurs when the shadow of the observer is projected on a cloud. Sometimes one, sometimes two, three, and even four bright coloured circles are seen in such cases, and they are so placed that the line passing from the centre of the sun through the eye of the observer, passes through their centre. The fourth circle is seldom seen complete; it is called the *circle of Ulloa*. There is an analogous phenomenon which explains *anthelia*:—when the sun rises behind a hill covered with trees or brushwood, the spectator in the shadow of the hill may observe all the small branches projected on the sky, not

ANT

opaque or black, but brilliant and silvery. These small branches act in the same way as the globules of vapour in the phenomena of *crowns* (*q. v.*) and *antheia*. This action is termed *Diffraction, q. v.* To the same cause is referable the beautiful colour of spider's threads, and of the motes in the sunbeam.

Antichthones. People that dwell at two parts on the surface which are however equal in latitude. Their seasons will of course be reversed, the winters of the one being the summers of the other, and so throughout.

Antipodes (*ἀντι, ποδς*, feet opposite). A term applying to the inhabitants at two opposite extremities of a diameter of the globe. It is clear, then, since degrees of latitude are measured north and south of the equator, and the intersection of a diametral plane, with the surface (or the circumference of a circular section of the mass of the earth), divides it into two equal parts, that the antipodal places must have the same latitude, the one being, however, north latitude, and the other south latitude. Again, if longitudes be measured for half the circumference eastward and westward, it is manifest that these places must be always the one in east, the other in west longitude, unless they be on the zero meridian line, and that the sum of the number of degrees representing their longitudes will be 180° . If we reckon longitude all round the globe, as we commonly do now, the difference of the degrees of longitude will be 180° . Everything will naturally be just reversed in reference to the inhabitants of places, the antipodes of each other. The noon of the one is the midnight of the other; the longest day of the one, the shortest of the other; and they have summer in the one place and winter in the other. The average length of day in both is of course the same throughout the year. The opinion that there were antipodes was a fruitful subject of ridicule in ancient times; and in the middle ages it was deemed heresy to hold it. Columbus had, perhaps, as much difficulty in procuring any support in his expedition on this ground as on any other. "Tempora mutantur, et nos mutamur in illis."

Antiscii, or Antœcii (*ἀντι, σκία*, or *ἀντι, δίαση*). When any distinction is made between the two words, the former is the more general, referring to persons living in different hemispheres, and at similar, though not equal distances, from the equator. The Antœcii are those who live at equal distances from the equator (same number of degrees of latitude north and south), and under the same meridian. The sun, therefore, passes their meridian at the same moment. When it is summer with the one also, it is winter with the other, and *vice versa*.

Aphelion. The greatest distance of a planetary body from the sun is called its aphelion (*ἄψω, ἑλίου*, from the sun). The aphelion of the earth and the apogee of the sun are the same. The aphelia of the planets change their position in successive

APP

years. The axis of the planetary orbit moves, as we have seen (**ANOMALISTIC YEAR**), and the aphelion, which is just its one extremity, moves with it. It was usual to measure the anomaly from the aphelion, but the aphelia of the comets are not generally visible, and therefore, to secure uniformity of measurement, the perihelion has been adopted as the point of departure in all cases.

Apogee. The point of maximum distance from the earth of any heavenly body. It is only important with regard to the sun and the moon. The apogee of the former occurs at the same time as the aphelion of the earth. The sun is often considered as moving round the earth. The moon does move round the earth. The apogees in these two cases move themselves, but move regularly. The apogees of the other planets move very irregularly. The motion of the earth has in their case to be compounded with the motion of these bodies themselves. We are in apogee about July 1st. The progressive movement of the sun's apogee is very slow. The moon's apogee moves rapidly and completes a revolution in 8232 days, or nearly nine years. That is about $6'.41''$ per day. The fact is very important in the theory of tides.

Apparent Magnitude and Figure of Bodies is different from their real magnitude and figure. A straight line for instance, drawn horizontally in the air, will appear to us circular. Sometimes, again, a straight line, when it all lies in the line from our eye to any one point of it, appears as a simple point. A surface, again, in which, if extended, the eye itself would be found, would appear to us as a line; and a solid body always appears to us a mere succession of surfaces, sometimes so seen that we believe that the body is solid, but if at a great distance not readily to be discerned from other surfaces. An angular or irregular body, again, appears always at any considerable distance more regular than in fact it is, because its little projections and irregularities, subtend very small angles to the eye, so small indeed, as easily to become insensible. So a long line of lamps seen from a distance appears only one continuous blaze, from the gradual diminution of the optical angles subtended by the distances between them. In astronomy, the *apparent magnitude* of an object is the angle which it subtends at the eye. It will therefore, abstracting refraction, which operates in all cases, diminish in inverse ratio to the distance. It will be evident also, even without mathematics, that it will be largest when the body is nearly perpendicular to the line of direction from the eye, and will vanish, becoming a point, if it were to appear in that line of direction. The heavenly bodies, however, being solid, this last consequence could never happen. Were they perfect spheres, we would not require to take into account the first cause of error. In measuring the apparent magnitude of stars, or of the sun and moon, we must recollect that their different points are subject to different influences from refraction, and to a very slight extent from

aberration and parallax, and that sometimes a body appears larger in one dimension, and proportionably smaller in another, than it really is.

Apparent Motion is the motion which a given body seems to us to have. Now, we refer all motion naturally to the eye. If, then, it be itself in motion, as when we travel in a steam-bus or railway carriage, we consider a body actually in motion, conceiving the eye to be at rest. The consequence is that we combine the two motions of the eye and the body into one, which we attribute entirely to the body in question. Not that we always add or subtract the two motions, for this we only do if the lines of motion be parallel, and if the directions be opposite or the same; but we compound them together as we do two forces, and attribute the resultant to the body which is in reality moving only with the one velocity. Even, however, when the eye is at rest, there is a distinction between the real and apparent motions. Motion is, of course, measured by the spaces passed over, and the eye has no direct measure of these spaces, but by the angular distances of the optical lines. If, then, a body

move from A to C, the space from A to B will appear equal to that from B to C, supposing the angles $\angle XAB$ and $\angle XBC$ equal to one another; and if the body be moving uniformly it will take longer to describe BC than AB, and since these appear equal, will appear to move slower in that part of its motion.

Apparent Position. When we want to simplify some observed phenomenon—by taking into account the effect which some cause with which we are acquainted will have in modifying it, or when we want from a true observation, at a particular point, to discover what would have been found by observers at some station of reference—we call our original phenomenon *apparent*, and the resulting and reduced phenomenon *true*. The name in one application of it is perhaps improper, but it is warranted by use. Thus, when we observe a star's position, we subject our observed result to various modifications before recording it. There is, in the first place, refraction, by which the star is made to appear higher above the horizon, than it would otherwise appear. We require, therefore, to allow for this, and to place our star nearer the horizon, than our

observation would lead us to believe. Then the aberration of light alters the direction of the ray which we see, from the true straight line from our eye to the star, and we must therefore take into account this cause of error. Nutation again changes the apparent position of the star, and we must rectify our observation for this also. By allowing duly for these, we will be able to arrive at the true position of the star from our point of view. But this observation would be only of use to ourselves, to compare it with subsequent observations from the same point. We therefore deduce from this the star's apparent position as seen from the centre of the earth, and so, as all observers reduce their observations in this way, the work of each is valuable to all. The *apparent place* of a star, then, is its place as observed at first, subject to all these causes of error, and its *true place* is when we have reduced our first observation, to obtain the direction of a straight line drawn from it to the centre of the globe. The apparent horizon is a good illustration also of the modifications introduced by astronomers, to render all observation valuable to all. The sensible or apparent horizon to a man at the surface of the earth is the circle, in which a plane, tangent to the surface of level water at his position, would cut the imaginary celestial sphere. If, again, he be a little elevated above the earth, the apparent horizon will be the circle, in which a cone touching the earth's sphere, and having his eye for the apex, would cut the celestial sphere. The real or rational horizon is the circle in which a plane parallel to the tangent plane at the surface, or immediately under an elevated position, would cut this sphere. The apparent conjunction of the planets, when the line from the eye passes through their centres, as distinguished from their real conjunction where the centres of the earth and of the true planets are in one straight line, is another illustration of the same necessity of correcting observations.

Apparent Time. See TIME.

Approximation is used in physical science to express a result which we are justified, according to the laws of probability, in taking as the result of a certain observation. Thus, let us observe the place of a star upon various occasions, and at various places, such, that it ought to be observed in the same position if no disturbing cause intervened. If we know the nature of these disturbing causes, we will observe so as to have them act in different ways, and, as far as we can guess, neutralize each other. Owing to disturbing causes, then, in external nature, and owing to the imperfections to which all quantitative observations are liable from the limitation of the observer's mental and physical powers, we shall have different results. The probabilities are, that these external and personal disturbing causes will act as often in increasing as in diminishing the result, and, in consequence, we approximate to the true result by taking all the

APP

observations together. The most usual method is by merely adding all the numerical results obtained, and dividing by their number. This approximation, if grounded on a sufficient number of observations, may be safely relied upon. Approximation, mathematically considered, arises from a different cause, the inadequacy of any numerical system to represent every kind of quantity. Thus, in attempting to find the numerical value of the side of a square or cube, whose area or volume is given numerically, we are often obliged to use mere approximations to the truth. The same will be the result of attempts to find numerical values satisfying equations of the higher orders in most cases. Generally, however, in this approximation we are able to assign the *limits of error* with perfect mathematical certainty. This, in the other case, we are unable to do, although we can attain to mathematical certainty as to what result of a series of observations, we are bound, as rational beings capable of calculating chances, to employ.

Appulse. When the moon passes very near a star, there is said to be an appulse. The precise moment of its occurrence is very carefully observed. We find it of the utmost use, when we wish to determine very accurately the longitude of a place, and when we wish to correct the errors of tables, to know the exact moment of appulse.

April. The fourth month of our year. The sun during this month is passing through Taurus. The word is derived from *aperio*, from the opening up of the treasures of the earth after the passage of winter.

Apsides. Those points of a body's path where its motion is at right angles, to the line to the centre around which its motion exists. They are the same points as the apogee and perigee, the apuclion and peribclion.

Aquila. A fine constellation in the northern hemisphere.

Ara. A constellation of the southern hemisphere, under the tail of Scorpio. It contains three stars of the third magnitude. The myth is, that it was the altar on which the gods swore fealty to Jupiter, before the war with the Titans.

Arch. The theory of the equilibrium of the arch, is one manifestly of great importance to the practical builder. Frequently cases occur in his practice where it is desirable that a solid road should be made over some impassable spot, without completely building up the included space. If he should attempt to throw a straight rod, or line of way over this space, its own weight frequently, and almost certainly the passing of any considerable mass in addition to that above it, would break down the structure entirely. Every part of the bridge between the solid piers on which it would rest, would be solicited by a downward force of gravity, due to its own weight. The part above the piers could not obey this solicitation, and so there

ARC

would be a force endeavouring to turn the different parts of the bridge round these different points. Thus at any point in the middle, suppose C, in the figure, there would be a downward force due to the weight of the mass, C. Let us

forget for the present that the whole of the line, A C B, is composed of parts quite as heavy as C, and examine the result there, if A C B were simply a straight rod without weight, which sustained the heavy mass, C, upon it. It is evident that the same result with certain modifications increasing its effect, would occur at all the points of A C B. Let us suppose now that the part B C is removed, and that only A C remains, with the mass, C, attached to it, A being a fixed point to which the stiff rod, A C, is attached. The mass, C, tends to fall straight downwards in the line, C D. But that it cannot do. It moves under one condition, that it shall always be at the same distance, A C, from the immovable point A, to which the inflexible rod, A C, attaches it. In fact it would just be as if we described a sphere round A, with A C for its radius. The circumference of the sphere includes every point in space at the same distance from A that C is, and so far as the connection of C through the inflexible rod with A is concerned, the ball, C, cannot move but along the circumference of this sphere. Then again, gravity always takes it straight downwards. It can only move then in a downward direction—right down vertically, along this sphere to which the rod fastens it. So, suppose that the plane of the paper is vertical to the horizon, the ball C, must describe whatever motion it can in that plane, and also in the sphere; therefore manifestly in the vertical circle, A C F. If we suppose A C similarly taken away, and B C a rod inflexibly fixed to the immovable point B, C could only move along C E. Now, if A C B were perfectly rigid, that is, if B C or A C were stiff enough absolutely to produce all the effects which are destroyed in their removals, the point would remain quite steadfast at C. But they are not so. B C tends to act a little as if it had been removed. It does not do the full complement of work in resisting the motion along C E that a quite inflexible rod B would do. Neither does A C in resisting the motion along C E. Seeking therefore to move in both directions, the body C moves in a sort of middle one and goes down, suppose to the point G. This line, C E, through which C falls, will quite evidently be longer or shorter as the beam is looser or stiffer, less or more flexible. If the

ARC

but were quite inflexible it would be absolutely nothing. Take the new circumstances then. In falling to the point G , the mass has obeyed either of the laws which bound it to the spheres, because it ought to obey both, which were contradictory. It has nevertheless fallen to G . The masses $A C$ and $B C$ then have become distended to $A G$ and $B G$. They have in fact been each pulled out and consequently weakened. The cohesion of their particles has been so far diminished, and they are less able to bear new weights than before. This tendency to sink and to damage the strength of the mass, and ultimately to tear it possibly asunder, has been acting at all the points of $A B$, and not alone at C : we can fancy then that the mass, $A C B$, will take the lengthened out form represented in the figure, in consequence of its weight.

Again, when the straight rod, $A B$, has reached this form, $A C B$, is it any more secure? Unless somehow or other new forms have been brought into play by this curvilinear shape, it is evidently not one whit more—rather something less. Every part of it possesses the same weight as before, and that tends to carry each part downwards in a new circle, $G H$ and $G I$, and the resistance which $H G$ and $G B$ can offer, the amount by which they are inferior to perfectly flexible rods is less than before, generally, with some bodies not necessarily, however. We must examine, then, this new case, because if we find that no new forces are introduced by the curvilinear figure, it will be clear that no straight roadway can bridge over a space, and also that no hanging chain, like $A C B$ in the last figure, can do it. We find that they can in practice to a certain extent, and we must examine therefore where their source of power is—how they are able to resist this continual dragging downward inseparable from them in virtue of their weight. To take up again the case, therefore. Let $A G B$ be the form of the line to which the weight, G , hangs as before.

Let us adopt a standard of length for the representation of force, and suppose, for example, that $G K$ represents in length, as it does in direction, the force of gravity. This then acts upon the mass, $A G B$, and the ball, G , and will not

ARC

permit rest in consequence of the imperfect inflexibility of $A G$ and $G B$, unless some force contrary in direction and equal in magnitude to $G K$ be somehow evolved, or some forces equivalent to such a one. Let the line $G F$ ($G K$ produced) represent this. Then, as we can only conceive of forces acting in matter, we can only obtain these required forces along the rod, $A G$ and $B G$. According, therefore, to the proposition of the composition of forces (see FORCE), if we draw $F E$ and $F L$ parallel to $B G$ and $A G$, forces which would be represented in magnitude and direction, according to the standard we have adopted by $G L$ and $G E$, would be equivalent to $G F$. If then such forces can be, and are called out in the circumstances, there will be an equipoise to the force, $G K$, representing gravity and equilibrium so far as that goes. There would be equilibrium therefore thus so far as G is concerned. But as regards $A G$ and $B G$, would there also be equilibrium with those forces which are thus called out in these rods alone acting? And is there not besides in fact an equilibrium as regards these rods? Why do these forces not send the pieces, $A G$ and $B G$, away upwards through the air, tearing asunder the connection at G ? Evidently because the rocks are there to prevent it. The points A and B are fixed points, and they prevent it. $G A$ and $G B$ are pushed against them by these forces and away, but they give back a force equal and opposite, and represented by $A D$ ($= G E$), and $B H$ ($= G L$) in direction and magnitude. They therefore counteract the forces, $G E$ and $G L$, and there is equilibrium there also. There is therefore a pulling force exercised on A and B respectively, $A D$ and $B H$, and there is again a tension equal and opposite to that, and keeping the rods in equilibrium. These latter pair of forces are, however, required for the counteraction of the weight G , and the result therefore is, that the three, $G E$, $G D$, $G L$, produce equilibriums at G , while the forces $D A$ and $B H$, pulling A and B downwards, are transmitted from G , the origin of the action. If, therefore, the bars $A G$ and $B G$ are strong enough to resist the disintegration which the transmission of these tensions might produce, if such a force, first acting at G , and transmitted by its cohesion to the next particle, and by it to its neighbour, and so on till A and B , find no place in the mass of the rods where the cohesion is a smaller force than itself, and therefore incapable of resisting it, there will be equilibrium.

When once the equilibrium is established, it will evidently not at all matter how the relation which the whole arrangement holds as regards any external object, e.g. the horizon, be changed, if there be no change thereby produced in any of the acting forces. Let us suppose that the figure which we have described is turned downside up, and that it makes, in consequence, such an appearance as in the figure at the top of the opposite column. All the circum-

ABC

stances of import in the case will be quite reversed. In order that this reversal shall be

complete, however, it is evident that the force G_K acts upwards, instead of downwards, and is, in fact, a prop now instead of a weight, when the equilibrium is established.

We shall take a more complex case, however, of the equilibrium of chains, which, as more readily intelligible to the learner, we thus take, as it rests on quite the same principles, as introductory to that of arches. Suppose that a weight, C , is attached to the point C , belonging to a string, A, B, C, D, G , which is incapable of stretching, or, in fact, of motion, and that we want to find the tensions that act along the string, by which the equilibrium is kept up, and the weights that must be hung at the other points, B and D , for this purpose.

Let CT , the equal and opposite strain, be compounded of CS , CE . Then the tensions SC and CE , in the strings BC and CD are needful to preserve equilibrium at C . But not only there is equilibrium necessary. It must be also kept in BC and CD . There must, therefore, be equal and opposite tensions. There must be a force, $BF = CS$, and a force $DR = CE$. Let these, then, be measured off. Now, if weights be at all hung at B and D , the direction of their counterbalancing forces must be vertical, because they themselves must hang vertically. Draw BK and DN , therefore, vertically through B and D , and draw the lines FK and EN parallel to BA and DG . Complete now the parallelograms FL and EM . Then the force of gravity acting at B , i.e. the weight to be put at B , will be represented by the length BK , and that at D by DN , and the tensions acting on A and G , the fixed points, by BL and DM . Hence we have been able, given the figure which the polygon is to assume, to find the weights which must be suspended at all but

ARC

one of the angular points of it, and the tensions by which its strings will be stretched.

The exact converse of this proposition depending, therefore, on the same methods of proof, would be — given the strain on the prop at c (the whole figure being inverted upward), required the strain on the props that must be placed at B and D, in order that there may be an equilibrium in the whole system.

It is evident that we might carry on this method of discovery, whatever might be the number of the points, B, C, D. If there be more of them, it would just be necessary to repeat the process the oftener, but on the same principles exactly. If there were so many that the whole space between A and E was so filled that it would be scarce possible to distinguish the difference from a curve, as in a chain of very small links, where each link is a straight line, yet, from their closeness the whole wears the appearance of a curve, there would be no difference in the principle. Finally, if we suppose the lines corresponding to the links (*i. e.* the sides of the polygonal line) to be infinitely small—smaller than anything which we can imagine—in fact, a curve, the same thing exactly would hold good. Given the form of the curve, and the weight which it was to bear at one point, it would be possible to tell how much must be borne at every other point. If, instead of having one of the weights thus given, such a condition connecting them were to be given as this:—Required the form of the curve which would be that of equilibrium when the weights would correspond to the lengths of the infinitely small polygonal sides, a special curve would be found out of the name of the *catenary* (*q. v.*) to satisfy these conditions.

The inverse of all these problems on chains or rods, where weights fall down, would be like problems on rods which props hold up, which props, therefore, sustain a certain amount of measureable pressure. Suppose, now, we consider such upright polygonal lines, where there are weights acting, as in the suspended ones, and where no props are brought into play. Let a given weight be placed at the point D; it is required to throw what weight will have to be put on at the points C, E, G, H, so that equilibrium

will result. Suppose the weight at D to be represented by DQ in direction and magnitude.

ARC

Then since DQ can be decomposed into forces DT and DT' , opposite and equal forces to these can neutralize. Suppose, therefore, a force in the direction TD , instead of DT , a force of equal amount, in an opposite direction, must act on the bar CD . Let it be SC . Then draw CP perpendicular as before, and SP parallel to CB , and complete the parallelogram $PCOS$. Then SC will represent in direction and magnitude the tension on BC and CP the weight required. So that equilibrium may be produced, the tension in CD meanwhile remaining equal to TD , one of the components of DQ . Carrying the same principle round to all the points, we can evidently get values for the weights to be placed at B, C, E, G . We shall seek then to gain some more accurate formula for the value of CP , which we can thus obtain by geometry.

It is a well-known trigonometrical proposition that the sides of a plane triangle are proportioned to the sines of the opposite angles. Our readers will find this demonstrated, if they do not already know it, in any work on Trigonometry, and in most on Geometry. Hence $DQ : DT :: \sin. D T Q : \sin. D Q T$. Now, $\sin. D T Q = \sin. T D T'$, because $T D T'$ and $D T Q$ are supplements of one another. Also, since $D Q T$ and $Q D T'$ are equal, $\sin. D Q T = \sin. T' D Q$.

Hence the formula takes this form:—

$$DQ : DT :: \sin. T D T' : \sin. Q D T'.$$

Now $TD = CS$.

$$\text{Hence } DQ : CS :: \sin. T D T' : \sin. Q D T'.$$

Again, $CS : CP :: \sin. C P S : \sin. C S P$, or by the same reasoning as before,

$$CS : CP :: \sin. B C P : \sin. B C D.$$

Multiply the ratios; $DQ : CP :: \sin. B C P \times \sin. T D T' : \sin. Q D T' \times \sin. B C D$.

$$\text{Or, } DQ : CP :: \sin. B C P \times \sin. C D E : \sin. Q D E \times \sin. B C D.$$

Now, CP is the only unknown quantity of all those here given. DQ is known, as representing the weight; CDE and BCD are angles of the adjacent sides of the polygonal line, and the other angles, BCP and QDE , represent the angles made with the successive sides by the vertical, which is a datum also given. It becomes possible thus, given the curve in the sort of arch that is to be described, and the weight that is to lie at one point of it, to find the weights that must lie upon the others.

This is one form in which the problem of the equilibrium of arches frequently comes before us. Given a certain arch or bridge of a curving form, and supposing a certain weight hanging on one part of the arch, what weight ought to be attached to the others to keep equilibrium? Or, as generally, a weight is attached to some and not to others, it is required to know what weights these are whose downward force the cohesion of the bridge materials must be able to resist, so that when a certain weight is laid on one part of the bridge, it may not break down

ARC

at any part. This problem is, given the bridge, and the weight at a certain point, required to find the strain at all other points of the bridge. The problem, however, more usually presents itself in the inverse form when the bridge is to be built, and knowing certain data of the weights which it will have to resist, we seek to discover the form which we ought to give.

Thus, let D be given, and the weights represented by DQ , CP , BO , and also the direction of DC , and DE , it is required to find the figure.

Draw DQ vertically between CD and DE , and

complete the figure $DTQT'$. Make CS equal to DT , and join SP . Draw CB parallel to that and PE parallel to CS . Then making BC equal to the given side, make $BG = CR$, and BO vertical equal to the given length. Join GO , and draw BA parallel to it, and OA to BG , and so on.

Following the same method, for the sake of discovering the unknown quantities here, that we knew before, we have—

$$DT = \frac{DQ \cdot \sin. Q D T}{\sin. C D E}$$

This gives TD or CS . Then CS is known, CP is also known, and the angle SCP is the supplement of TDQ , and, therefore, is also known; so that thus, by trigonometrical principles, we can easily find SP or CR (*Euc. I. 84*), and $CS P$, which (*Euc. I. 29*) is the supplement of $RC S$.

These, then, are the two problems, inverse one to the other, with which the architect has to do. Given the bridge—what strains will be brought on it, all its parts, by the placing of a certain strain on one; and, secondly, given the utmost strain which each part will require to bear to discover a form of arch—one or two data as to its character at the crown of the arch (*e.g.* the angles TDQ and $T'DQ$) being given—which shall give equilibrium under the pressures to which these strains are due.

In the usual case, the form which it is desirable to give the arch is that of some curve, or rather of some polygonal line, very nearly approaching a curve, and whose peculiarities can be best investigated on the principles of the differential or integral calculus, by supposing it a curve. In that case, the angle XCD , which is the supplement of BCD in the last figure, becomes the angle between the tangent to the curve at C , and the curve itself. This angle

ARC

between a tangent to a curve, and the curve itself, the angle of *contact*, as it is called, varies as the curvature of the curve varies. For example, if we describe two or three circles all

touching one common tangent, it will be manifest enough (fig. 2) that the angle of contact is much greater in the smaller than in the larger.

Now, there is supposed to be a circle, which coincides the nearest possible with every curve at each point of its curvature. It is merely supposed, for the sake of assisting our notions of curvature, by referring them to the readily intelligible curve of the circle. However, these circles of curvature are supposed through the given point, and two points of the curve indefinitely near it, and, therefore, do closely coincide with it, and represent its curvature at the point. The radius of the circle is called the *radius of curvature*. Now, the angle of contact of which we have spoken, corresponding to $\angle C D$ in the last figure, varies inversely as this radius of curvature does—that is, is reciprocally proportional to it. Also, the angles $\angle P C B$, $\angle P C D$, in that figure are equal to $\angle P C D$, $\angle P C S$, in this, because the tangent at a point is indefinitely near in direction to the very small sides of the polygonal figure substituted in idea for the curve, and its direction may, without error, be substituted for theirs. Now, $\angle P C D$ and $\angle P C S$ are supplements, and their sines are therefore equal.

Now, we saw already, in the proof above that where the same circumstances, known and unknown, were considered, with only a different set, known and unknown, from these in the last case, that

$$DQ : CP :: \sin. BCP \times \sin. CDE : \sin. QDE \times \sin. BCD.$$

$$\text{i.e. } DQ : CP :: \frac{\sin. CDE}{\sin. QDE} : \frac{\sin. BCD}{\sin. BCP}.$$

That is, each weight is directly proportional to the sine of the polygonal angle corresponding, and inversely to that of the angle of the polygonal side, adjacent with the vertical. The polygonal angle is the supplement of this angle of contact, and its sine is therefore equal to it. With two adjacent sides, the weight inversely proportional to the sine of this angle of the tangent, with the vertical, would give quite correct results; but in considering two remote sides,

ARC

another element has to be introduced, which we eliminated from consideration, rightly in the case of the two adjacent sides, and the full formula would be—

$$DQ : CP :: \frac{\sin. CDE}{\sin. BCD} :$$

$$\frac{\sin. PCD. \sin. QDE}{\sin. BCP. \sin. QDE}.$$

In the case of the two adjacent sides actually represented in that figure, $\sin. QDC$ and $\sin. PCD$ are equal, and may, therefore, be struck out of the proportion. In the case of the curve, where, having lost sight of the sides from their indefinite minuteness, we ought no longer to consider any two as adjacent, we must not omit them. Remembering, then, that $\angle BCP$ and $\angle PCD$ are supplemental in the case of the curve and their sines equal we find, that the weight varies as the fraction

$$\frac{1}{\text{Radius of curvature} \times (\sin. sCP)^2}.$$

This gives us the actual weight which may be put on at each spot. But it is desirable to know, instead of that, the actual thickness up to which we may lay on a uniform material, instead of as thus. Now, the actual weight of a certain length, near any given point, will not all lie pushing down with the same force, as if at the top, when on the inclined part of the curves. In fact, an equal mass of stone at the curves, and on the side of the curve, would clearly not hang on an equal length of the curve at all, but on a length, which would be inversely proportional to the sine of the angle sCP at the place. Hence it would be necessary to heap up the stone in this proportion, and the height CP might be represented by the formula

$$\frac{1}{(\text{Radius of curvature}) \times (\sin. sCP)^2}.$$

Again, $\angle P C S$ = complement of $\angle S C H$, and therefore $\sin. sCP = \cos. sCH$, and the formula becomes

$$\frac{1}{\text{Radius of curvature} \times \cos. sCH} = \frac{\sec. sCH}{\text{Radius of curvature}}.$$

The methods of finding the radii of curvature, upon which the theory of equilibrium of arches is thus seen to depend, rest upon principles belonging more peculiarly to the higher mathematics, and are technical; but we trust that, so far as we have gone, the reader, with a little trigonometry, or taking for granted the trigonometrical formulae which we have required to state, will not have found very serious difficulties.

Taking this formula, then, for granted, we

ARC

shall compare the different parts of the arches, one with the other. The weakest place we should naturally expect to be the crown of the arch. All the masses on each side tend to pull it down, and it is least supported obliquely of any. This we actually discover generally in the arch. At the crown, the angle $s c h$ becomes $= 0^\circ$, and its secant, therefore, equal to 1. The quantity, $\sec s c h$, is then at its minimum value. We cannot compare, however, the other quantity included in the formula, until we know the special curves.

Again, comparing the strength of two arches, it is evident that it will be sufficient to compare the weights which each can sustain at this their weakest point. If a pressure be brought on the weakest part greater than it can sustain, then no matter how great the capabilities of other parts of the arch may be, it will fall. Comparing, then, the weights at the crown, we find $\sec s c h$ to be equal to 1 for both, and, therefore, the strengths are respectively in the inverse proportion of the radii of curvature. To take a practical instance of this, the radii of curvature of arches of the following curves, each with a span of 100 feet, and a rise of 40 feet, are given in the table:—

Segment of a circle.....	51.25
Parabola.....	80.125
Ellipse.....	62.5
Hyperbola.....	87.417
Catenary.....	86.9

Hence the parabola, having the smallest radius of curvature, can bear the greatest weight at the crown, and the ellipse, having the largest, the least. In accordance with this fact, it is found that there are very few elliptical arches of large span, in proportion to their height (in this instance the disproportion is not nearly so great as it frequently is), where the crown has not sunk a certain distance. Where the arch is so low, the circle that it resembles becomes very large—i.e. the radius of curvature is very large.

The formula, then, which we have found

$$\frac{\sec s c h}{\text{Radius of curvature,}}$$

expresses the weight of a superincumbent mass of uniform substance, as masonry, under the pressure of which all the parts of the curve will be in equilibrium.

It is easy, therefore, by mere application of this to a given curve, whose laws are known, to solve this problem:— Given the intrados of a bridge (i.e. the inner curve), to find the

height of the superincumbent wall, or extrados, at each point, so that under its pressure there

ARC

may be equilibrium. We might go along, taking one given curve (see fig.) marking off at each point of its length, the values of the formula

$$\frac{\sec s c h}{\text{Radius of curvature,}}$$

and so, joining our consecutive points thus obtained, coming to a polygonal line, while the closer our points were brought (as for a perfect solution they would need to be indefinitely close), this line would become more and more curved, would give nearer and nearer the complete curve of the extrados.

The inverse problem, to find the intrados when the extrados is given, is frequently also of very great use. It rests on the same principles, and we shall, therefore, not give any further account of it here. The one is required when we require a special form of arch for the transit of vessels, and when it is not of essential importance what sort of passage way there may be, so that there be one at all. The other is of chief importance, where the bridge is to be used only as a roadway.

There are various other matters of considerable importance in the theory of arches, which the very limited space at our disposal compels us to pass over. A number of the practical details connected with it are given in the article on BRIDGES, to which we must refer. For the theory of the Arch, the reader not acquainted very intimately with mathematics may refer, with great advantage, to Gwilt's treatise on the subject, to which the present article is much indebted; and, for the fuller investigation of it, the admirable article in the new edition of the *Encyclopædia Britannica* will supply ample means. See SKEW-ARCH.

Arch in Architecture. The arch, as a mode of passing from one pillar or upright support, in Architecture, to another, has had in practice various forms; and these are not uncharacteristic of Architectural styles prevalent at various epochs. The present Dictionary not including matters relating to the Fine Arts, we shall simply specify that the Romans put in practice the round arch and the vault. The pointed or Gothic arch, succeeded to the circular one; out of this grew the foliated arch, or arch of the form below, in which the foliations A and B were originally meant to give the arch greater power to resist a vertical pressure applied at C. Various modifications, in the way of ornament, grew out of this simple case of foliation; but into these we shall not enter. There is further the ogee arch, or arch of double curvature, as below. This arch has many ornamental modifications. See ARCHITECTURE, DOME, &c.

ARC

Archimedes, Principle of. We owe to the immortal Syracusan the establishment of the principle which may be termed the foundation or corner-stone of rational statics, viz., the principle of *the equilibrium of the lever*. The principle itself is now well known; it is, that a lever, loaded with two weights, on opposite sides of the fulcrum, is in equilibrio when the weights are inversely proportional to the length of the arms at whose extremities they respectively hang; to which may be added, as a supplement, that the pressure on the fulcrum of the lever is then exactly the sum of the two weights. The demonstration given by Archimedes is a very simple and fine one. Claiming it as an axiom in mechanics—either as self-evident, or a result of universal experience—that the lever will be in equilibrio when two equal weights hang at the ends of equal arms, he first takes the case of *commensurable* unequal weights; and, by the artifice of dividing the two into different numbers of equal weights, and transporting these by equal distances to one side and the other of the lever, he easily arrives at the general conclusion. The theorem is then extended to the case of *incommensurable* weights, by a species of reasoning familiar to all students of Euclid. Various authors have criticised the process of Archimedes, with a view to simplify it, or to remove fancied defects. It cannot be said that much good has followed, at least if we except the efforts of Stevin and Galileo. There are some fine remarks on the whole subject in the preliminary chapter of the *Mécanique Analytique*.

Archimedes' Screw. A machine for raising water, consisting of a pipe rolled round a solid cylinder. Sometimes we have a spiral groove cut in a solid cylinder, and a water-tight cover put over the cylinder. This arrangement makes the tube semicircular. It is less liable in this way, however, to accident, since the screw is not exposed. The cylinder is placed in water, so that the angle which the axis makes with the vertical be greater than the angle at which the thread of the screw is inclined to the right section of the cylinder. Let the reader take a pencil, or any similar cylinder, and mark a spiral round it with his pen. Place it then in the position we have specified, and let him suppose the figure before him to represent the Archimedian screw. Suppose it then just touching in water, the open end of the screw being just covered. It is clear that the water entering the screw at the open end, A, will *descend* the tube by its weight, until it reach the point where the screw again ascends, and, by the principles of hydrostatics, it will ascend so far above this as to be on a level with the outside water. Turn the pencil then on its axis. Then all the water in the descending portion of the screw will press downwards, and it will occupy a complete semi-circumference of the screw. All the water in the ascending portion, how-

ARC

ever, will require to be pressed up, but as it does not occupy so much space, in consequence of the screw having an upward tendency, it will not press against the other pressure, so as to prevent any effect from it. On the contrary, it will be pushed upward, and more water will enter at the open end. If the screw keep constantly turning, this process will keep constantly going on, and that in every turn of the thread. The water constantly will be sent rapidly through the tube upwards to the end of it, and can there be made available for any special purpose. The turning of the axis, in fact, just serves to repeat the action of gravity upon the water over and over again, and by this machine it is made to raise water effectually by pulling it downwards. We mentioned that the angle of the axis of the screw to the vertical must be greater than that of the thread of the screw to the right section of it (perpendicular to the axis). It will be readily seen that the angle of this section to the horizontal is the same as that of the axis to the vertical, and that if it were less than the angle of thread to this section, the screw would rise throughout its whole course, and none of the water would flow into it at all. The screw may, of course, be used horizontally, but no mechanical advantage is obtained by the carriage of water from one horizontal position to another. It is sometimes, however, found convenient. In the explanation which we have given, we said that the screw is just dipped, and no more, into the water. In practice, a good part of the screw is sometimes immersed. The explanation is the same as before, and we have only used the limitation in order to render the matter as clear as possible.

Architecture:—in its full generality, the *Science of constructing buildings suitable for specified purposes*. But the natural and laudable disposition of men to ornament buildings, erected with pains and labour, has converted Architecture from a portion of statical science into a chief department of *Æsthetics*. Nay, it is that portion of æsthetics to whose memorials we may the most surely appeal, in illustration of the taste, the genius, the manners even, of past Ages. But into this mode of considering architecture, we can in no wise enter here. Suffice it to say, that its three grandest monuments are unquestionably the Hall of Karnac, the Parthenon, and that Choir of the Cathedral of Cologne. These stand out purely and nobly, indestructible monuments of Architectural and Æsthetic power. If selection should be asked, there are few in this northern region, and with our northern ideas, who would not first exclude from competition, even the exquisite Parthenon. Between the Hypostyle Hall and the Cathedral, any one's decision might well waver.—There are several doctrines—which should be ever held *cardinal* in Architecture—so closely connected with *Mechanical Science*, that we take leave to embody them here, as

ARC

of established maxima. **FIRST.** Buildings being for us, we ought, as their *first*, to be their *final* aim. **SECONDLY.** Ornament ought to be superinduced on utility; never can it transgress this limit, without our getting into false taste. From these two maxima, many others follow. Let the modern architect adjudge by the *first* his rational admiration of some early Cathedral structures, in which there is not a Buttress without its mechanical import, or an Aisle without its interior employment and convenience; and then turn to his efforts to reproduce as a *modern* church, a turretted and pinnacled grotesque, in which the parts no more form a mechanical whole than do the parts of a confectioner's bride's cake; and what is worse, in which the interior—defaced besides by galleries choking up the arches—has not the remotest reference to the requisitions of modern Protestant worship. And let him equally adjudge, by the second maxim—unwarned as he has been by the failure alike of the *flamboyant* and the *perpendicular styles*, in which our pure Gothic had its termination,—in what manner he can explain *grotesques*, so utterly without meaning, now reproduced in sheerest and dullest imitation, but to which no devout—no living human Soul—can now attach one intelligible idea! In our modern vulgar, and lifeless, and absurd reproductions, not one living conception is embalmed. The great Cathedrals, of old times, are mostly incomplete: for instance, they have only one instead of two superb and symmetrical towers. It has become now a symbol of "correct and antiquarian fashion" to build even small churches with one, side and unsymmetrical tower!—Let us return to reason, and thus imitate those best of ancient times. An Architecture worthy of modern genius, fit for modern uses, helped by all modern appliances, and ornamented in accordance with the noblest of modern aspirations, remains to be created. Would indeed, that the Age could obtain one thoroughly good and free Stone Mason of unfettered genius!

Arctic. (derived from the Greek, *ἄρκτος*, a bear—from the proximity of the North Pole to the constellation—the bear), is used frequently as equivalent to Northern. The phrase *Arctic zone* is accurately applied to a circle having the North Pole for centre, and having a radius equal to $23^{\circ} 28'$ nearly. The *Antarctic zone* is a similar section of the earth's surface, having its centre at the South Pole. The *Arctic regions* is a phrase employed with reference to particular spots both of the earth and sky, and refers in every case to the regions adjacent to the North Pole. The poles are the extremities of an imaginary line round which the earth performs her diurnal revolution (v. *Pole*). The North Pole of the heavens is obtained by prolonging this line in the direction of the celestial sphere, and is the point where this prolonged direction meets the sphere. Of course it is not so much a point as a line of direction, since the sphere referred to is imaginary.

ARE

Arcturus. A well-known star in constellation Bootes.

Areas, Principle of; or Principle of the Conservation of. A principle in *Rational Mechanics*, of so general an application, that it can scarcely be called a secondary one. The first and simplest form in which this important principle can be presented, is the *Second Law* of the immortal Kepler. Having found that the planet *Mars* describes around the *Sun* an ellipse, in one focus of which the *Sun* is placed, he discerned soon after, that the law of the velocities of *Mars* could be expressed as follows:—The *radius vector* (i.e. the line joining the centre of the sun and the centre of the planet) sweeps over *equal areas* in *equal times*. So soon as the great German extended the fact of elliptic motion to *all* the planets, he recognized the law of the velocities to be *general* also; so that it could be stated that all the planets move around the sun with such velocities, that in *each* case the *radius vector* describes *equal areas* in *equal times*. Such the earliest discovery through *facts*, of the great principle of the *conservation of areas*. Let us attempt to describe it now in its full generality. Kepler's law extended to the case of one planet or orb encircling another; but it belongs to the most complex system, whose orbs are controlled by a mutual attraction. And in the following wise. Kepler's law, in reference to the planetary movements, expresses close approximations only; it would not be absolutely correct unless in the case of planetary orbs moving *independent of each other* around a central point. If the planets affect each other, *perturbations* ensue. But the principle of areas, rightly understood, holds good through all such perturbations. Take, for instance, a system of three bodies, such as the *Sun*, *Earth*, and *Moon*. If the orbits of the earth and moon were in the same plane, Kepler's law would be this:—The sums of the two areas described in equal times, viz. of the area described by the radius vector of the sun and earth, and the area described in the same time by the radius vector of the earth and moon, will always be equal. But the orbits are *not in the same plane*; hence a great complicity, not however affecting the principle of the conservation of areas. Because of the difference of *plane*, resort must be had to the device of *projection*; i.e. the areas in question must be projected on *some one plane*. Suppose one's self looking at these motions through a transparent sheet of glass, placed in any way, the motion of the two bodies would appear on that transparent sheet as if they were in one plane, and the areas described by their *radii vectores*, would, as seen on that sheet, have definite measures; it is *these last, or projected amounts*, which, in accordance with the principle of the *conservation of areas*, are proportional to the *times of description*. Apply this scheme or mode of thought, to our entire planetary system; i.e., look at the whole of it

ARE

through a transparent sheet, placed in any way, then the areas, as seen described by the *whole*, whatever their relations, will be strictly proportional to the times of description. The great Laplace even, saw the stretch of this principle but imperfectly. He conceived it rigorously true, if the major motions only were taken into account. It is certainly not so. Poincot has recently insisted that not only the motions of *revolution* of satellites, but motions of *rotation* alike of planet and satellite, must be held in view, ere identity can be predicated between spaces described in equal times, within a system internally balanced. Thus understood, the principle of the conversion of areas must, in every such system, be rigorously true. But without going to such rigour, one important and comparatively practical conclusion may be drawn. Reference has been made to the *projection* of such areas on a *plane*. However that plane is placed, the foregoing theorem is true. But although the proportionality of *areas* to the *times* of description, holds true with regard to *any* plane; the amount in size of the areas projected on the plane will manifestly depend on the *position* of the plane. Now, with regard to the solar system, as to any other system, there is at every given time one especial plane, on which the amount of the total areas described will be greater than their amount described or projected or on any other plane. That plane has been termed the *Great Equator Plane of the System*; and it is the highest result in expression, of the principle of the *Conservation of Areas*, that this *great equator plane* will continue *invariable in position* so long as the system is undisturbed from without, and carries on its motions, through the interdependency of its internal parts. If the position, then, of our own grand equator plane were determined, that position would be a fixed point by which after ages might decide whether and how far our condition has been affected by communion with external systems, or by our sympathies with the fixed stars.

Areometer. (*ἀραιός*, light; *μέτρον*, a measure). An instrument serving to measure the densities of liquids. The principle of the areometer is simply this, that any solid body sinks farther in a light liquid than in a heavy one. It is usually a small glass bulb loaded at the bottom with quicksilver, or small shot, so as to set it upright, and having a scale at the top to mark the depth to which it sinks in any liquid. In most cases, the numbers on the scale are arbitrary, and refer to arbitrary indices of the strength or weakness of a fluid (*e. g.* over proof and under proof) employed by merchants in testing the value of their purchases. Where the liquid should be lighter the purer it is, the degrees proceed from the bottom to the top (as in alcohol), and where its value is proportioned to its density, they go downwards

ARM

from top to bottom. As the density varies with the temperature, a thermometer is frequently placed alongside the graduated scale, and this is sometimes ingeniously constructed so as to serve as a sort of corrective against errors of observation on the scale of density. We give a figure of the instrument.

Artes. An equatorial constellation; the first of the signs of the ecliptic.

Arge. One of the great southern constellations. The star Canopus, of the first magnitude, is its most prominent star.

Armature. A French term partly adopted in English. There is no English one accurately corresponding. It is the name of the piece of iron attached usually to a magnet to prevent the dissipation of the magnetic fluid. The ordinary horse-shoe magnet is of the form represented in the figure, the poles *n* and *s* being opposite. The piece of iron, *A*, becoming by contact a magnet also, completes a magnetic circuit, each part of which acts and reacts on the other, as the coatings of the Leyden phial in the case of electricity do. For an ordinary bar magnet, it is usual to fix its magnetization by placing alongside of it another of the same form, but with its poles in directions opposed to those of the other, and to place two pieces of soft iron, one at each end, in contact.

Armillary Sphere. An instrument consisting of several brass rings, all circles of the same sphere, in the position which important circles of the celestial sphere have. Suppose that we have a celestial globe, along which are marked the following circles in their proper positions:—the *horizon*, the *meridian*, the *equator*, the *ecliptic* or circle of the *zodiac*, and the two *colures* (*q. v.*) (these all being *great* circles of the sphere, dividing it, that is, in two), and the two *tropics*, and the two circles which limit the arctic and antarctic zones (which four are *small* circles of the sphere), and let us suppose that rigid circular rims are made just to go round those lines, and the sphere then destroyed while these rims are connected with one another to remain steadfast in their relative positions, and mounted on a stand as the sphere was, we should obtain what is called the *armillary sphere*. The reader will readily understand how, supposing the centre of the sphere to be the position of a spectator at the earth, he will come to comprehend the *apparent* motions of the heavenly bodies and the significance of the references constantly made in describing the apparent places, to these elementary circles.

Artillery, a general name given to all arms used in war, which are too heavy to be carried by the individual combatants. These arms of course vary in characteristics according to their purposes. Some are employed for the attack or

ART

defence of fortified places, and others in the open field or during the course of an open field fight. The purposes of defence, in case of a besieged fortress, necessarily admit the use of heavy fixed pieces of ordnance; and it was in such circumstances alone that Perkin's steam-gun, so notorious several years ago, was ever deemed to be applicable. Probably one of the finest developments of ordnance during a siege, that has yet taken place, occurred in course of the recent siege and defence of Sebastopol. The artillery officer and engineer cannot fail to derive large instruction from the detailed account of this celebrated event, now on the eve of publication under the auspices of the French Minister of War. Artillery ordnance varies also according as its destination is for use on land, or on board ship.—A formal article on Artillery would be altogether out of place in a Cyclopædia like this; we shall dismiss the subject therefore with a brief notice of its connection with the progress of the mechanical arts, and its dependence on the condition of these arts. It were of course needless to advert to the enormous or rather the fundamental change that passed over every requisition of Artillery on the invention of gunpowder. The force of the projectile was given to it previously, by aid of the elasticity of bent cords or of a solid spring: on that invention, a small portion of powder created an explosive and propellant force, of the power of some thousand atmospheres. Since then there has been but one limit to the efficacy of that propulsion, viz., our mechanical ability to bestow on the tubes holding the powder and projectile, as much strength as would resist the lateral action of the explosive force, and at the same time consist with our power to transport the piece of ordnance easily. Resistance to this lateral force, and lightness,—these are the prime requisites of a modern cannon. Especially is it so in parks of artillery meant for use in the open field, whether these be the lighter sort of *flying artillery*, or pieces and batteries intended for comparatively stationary action. Of course *trueness of direction* is demanded of cannon as well as of the hand rifle: unfortunately this has not as yet been manifested in action to anything like the degree of perfection attained by the smaller rifle. This however is imperatively demanded by the growing perfection of that small rifle. Field artillery in one of its important applications is meant to open the way to the action of infantry: it ought therefore to be effective at a distance which will insure safety to the gunner, from antagonistic riflemen.—We are now at the opening of a great European war. It is said that France has greatly increased its artillery arm, and that the Emperor has selected a new and favourite gun. The arm with which Sir William Armstrong has strengthened alike the field and sea artillery of Britain, is understood to be an unusual acquisition. It carries *bars through five miles*, and is so light that two

ASC

or three boys may manage it.—Especial reference is made to article RIFLE in our Dictionary; and also to the more extended article by the same author in the *Encyclopædia Britannica*, new edition.

Ascension, Right, Oblique. Ascension is an astronomical term used for the purpose of referring a star to its exact position in the heavens, and so rendering possible the identification of the star. The north and south poles of the heavens are regarded as fixed points, and the equator is consequently a fixed circle of the celestial sphere. Suppose, now, that a meridian passes through a given star, that is, a great circle through the star and the poles, it will cut the equator at a given point. The distance of this point, in degrees of the circumference from one of the points where the equator is cut by the ecliptic (the vernal equinox), is called the *right ascension* of the star. The right ascension is sometimes given in time instead of in hours. The whole heavens appear, in consequence of the diurnal motion, to revolve once in 24 hours. The space between the star and the point of the visible heavens, where the equinox is at any moment, will be passed over at the rate of $\frac{24}{360}$ of an hour for each degree of angular measurement. To obtain the ascension given in degrees to that in hours, we reckon 4 minutes for a degree, with corresponding fractions for the lesser angles. We simply reverse the process in finding the ascension in degrees from that in hours. The phrase ascension is employed for this reason. The astronomical day is reckoned from the moment at which the first point of Aries (the point of the equator corresponding to the vernal equinox) passes the meridian. All the stars which have the same right ascension will seem to rise upwards from the horizon (if visible, and if not, may be imagined to do so), and to cross the meridian of the place at the same moment. The right ascension, then, as we have described it, measures the interval between the crossing of the meridian by the first point of Aries and by the star. A reference to figure No. 1 will at once

Fig. 1.

show that *q r* would be the right ascension of the star, *s*, upon the meridian, *x s r*. The other name *oblique ascension* is used to express the difference in the times of the rising of the first point of Aries and a given star. If we consider that while some stars upon the same meridian, and having, therefore, the same right ascension,

ASP

almost never set, while others almost never rise, it will be evident that there cannot be the same difference between the times in which the first point of Aries, and all the points having the same right ascension, cross the horizon, and as there is the same difference between the times in which they cross the meridian, the oblique and right ascensions must be represented by different numbers. The distance between that point of the equator which rises with the star, and the first point of Aries, is called the oblique ascension. To a person at the equator, however, whose horizon is a great circle passing through the poles, the oblique and right ascensions are identical. We call *ascensional difference* the excess of the right ascension over the oblique, or *vice versa*. The figure (No. 2) will serve

Fig. 2

to explain this, though the reader's safest way is to consider carefully for himself the various circles described, and all the circumstances mentioned. Without this, plane figures rather mislead than instruct. The star, *s*, will cut any circle which passes through *P*, and the other pole (as the meridian does), at the same moment that *r* does so, and *q r*, the right ascension, therefore, measures the interval between the passing of *q*, and all stars upon the meridian, *P T A*. But a star at *r*, for instance, will have risen above the horizon, *P E S*, long before *s*, and one at *s'*, for example, after it. The oblique ascension, therefore, is measured by the space between *q* and *E*, the point of the equator, which rises along with *s*, and as *q r* is the right ascension, *r E* is the ascensional difference. The oblique ascension and ascensional difference are transformed from degrees to time just as before.

Aspect. An astronomical term, almost disused. It is of interest only because it may be met with in old astronomical works of considerable value. The terms conjunction and opposition express the only two aspects of the planets (i.e. relative positions as seen from the earth), which are still named. At conjunction (*q. v.*) two planets have the same longitude; at opposition they differ by 180° in longitude; and in these 180° are the *trine* aspect, 120° apart; the *quartile*, 90° apart; the *sextile* 60° apart. The

AST

old characters used to indicate them are the following:—

Conjunction	♌
Sextile	✱
Quartile	□
Trine.....	△
Opposition	♌

These terms, obsolete in astronomy, are still found in abundance in astrological works—not all ancient yet.

Asteroids, or small planets, a group of bodies singularly insignificant in size, that revolve around the sun in planetary orbits, between Mars and Jupiter. Their relation to the solar system in general, being explained under SOLAR SYSTEM, we shall confine ourselves here to the statement of all that appears peculiar to the group, and characteristic of its position. The existence of a body or bodies, between Mars and Jupiter, seemed to be indicated by a remarkable *hiatus* between these planets (see BODE'S LAW),—the celebrated Olbers, of Bremen, ventured, about the beginning of the century, to assert that the application of telescopes to the search for planets occupying that place, would certainly be richly rewarded. In consequence of this suggestion, *Ceres* was discovered by Piazzi of Palermo, on the first day of this century; Olbers himself soon after detected *Pallas* and *Juno*, and Harding of Goettingen discovered *Juno*. This group of the four small planets, as it was termed, appearing to have verified the prediction and filled up the *hiatus*, curiosity and research were alike suspended, until stirred anew, in 1845, by the accidental discovery of *Astræa*, a fifth member of the group, by Hencke of Driessen. Many observers, in possession of suitable instruments, now rushed into the field; but none with so much perseverance and discernment than Mr. Hind, of the Observatory of Regent's Park, London. Up to the close of 1853, *eleven* new planets had been added to the group by this indefatigable observer, and while we write he continues his earnest and successful research. No fewer than *fifty-six* asteroids are already detected; but the probability is, that they count by *hundreds*, and that they form a stream or zone of small bodies occupying the place, and in so far performing the function, in the system, of the large planet which, according to Bode's law of the distances, might have been expected in the locality. They are essentially a *group*, to be viewed not singly but as a group. As the following table will show, they are nearly at the same distance from the sun; the periods of their revolutions very closely correspond; and in physical characteristics, for instance in *size* (some of them are not larger in surface than the kingdom of France); they are distinguished in the same way from all the chief planets.

Pandora discovered by Searle, of Albany.
Alexandra and the new planet by Goldschmidt.

Perhaps the first thing that strikes one, on glancing over this long and confused list of names, is the absolute need of a new and simpler mode of distinguishing the several Asteroids. This has been partially adopted, and must come into universal use. It is proposed that each Asteroid be indicated by a number marking its rank in the order of discovery, that number being enclosed within a small circle, thus:—

Cerea, . . . (1).
 Urania, . . . (30).
 &c.

This is evidently the only principle of numbering that could be permanent: any arrangement reposing on the distances of the Asteroids from the sun being ever liable to be broken up on the discovery of some new member of the group: the permanency even of this assignment, indeed, was recently threatened by a singular occurrence. On the 9th of September, 1857, Goldschmidt thought he had re-discerned Daphne, and published his observation under that idea. It turns out, however, that the body he saw was not Daphne, but must have been a new planet: (the "new planet" referred to in these tables). By the foregoing rule, therefore, its sign ought to be (47), and all signs subsequent to that would require to be changed. But such a difficulty is not likely to recur, and it may be got over in the present instance by numbering the planet when it shall be again seen, and shall receive some fantastic name. The following list gives the order of discovery, and of course the new conventional signs:—Cerea, Pallas, Juno, Vesta, Astræa, Hebe, Iris, Flora, Metis, Hygeia, Parthenope, Victoria, Egeria, Irene, Eunomia, Psyche, Thetis, Melpomene, Fortuna, Massalia, Læstetia, Calliope, Thalia, Themis, Phocæa, Proserpine, Enterpe, Bellona, Amphitrite, Urania, Euphrosyne, Pomona, Polyhymnia, Circe, Leucothea, Atalanta, Fides, Leda, Læstetia, Harmonia, Daphne, Isis, Ariadne, Nysa, Eugenia, Hæstia, Aglæa, Doria, Pales, Virginia, Nemansa, Europa, Calypso, Pandora, and Alexandra.

Passing, however, from external details to consideration of the interesting character of this system, we find on comparing the orbit of Euphrosyne with that of Ariadne, that the *mean breadth* of the zone, or ring within which the Asteroids lie, is 95716 of the mean distance of the Earth from the Sun, or about ninety-one millions of miles. But in consequence of the great eccentricity of several of the orbits, some of these curious bodies can adventure much farther than that into space. The planet Nysa, for instance, has an eccentricity so great that its orbit much more resembles that of a comet. It recedes farther from the sun than any of the others, and, with the exception of Hæstia, it approaches him the nearest. Of them all Hæstia comes nearest the earth; after it, in this respect, Nysa ranks. Euphrosyne and others have also very eccentric orbits. The inclination of the

orbit of Nysa, too—viz.: $8^{\circ} 58'$ —is not very distant from that of the orbits of Ariadne, Harmonia, Læstetia, Fides, Proserpine, Psyche, Pales, and Hygeia, so that it may, or rather must, frequently approach closely to some of these bodies. The inclinations, indeed, of Nysa and Hygeia differ by only six minutes, so that they are almost in the same plane. The longitudes of their ascending nodes, however, differ at present by 160° . It is scarcely necessary to call attention to the contrast presented by the inclination of the orbits of several of these Asteroids to anything that prevails in the other portions of our solar system. The greatest inclination known among the larger planets is that of Mercury, being $7^{\circ} 0' 59''$; the inclination of that of Pallas is, on the other hand, $84^{\circ} 42' 37''$; that of Euphrosyne, $26^{\circ} 25' 12''$; of Phocæa, $21^{\circ} 86' 5''$; of Atalanta, $18^{\circ} 42' 9''$; of Egeria, $16^{\circ} 82' 14''$; &c., &c. But their deviations do not involve any deviation as to motion from what the law of gravitation would induce us to expect. Although the ellipses are eccentric, and the inclination large, every one of these minute orbs obeys the three cardinal laws of Kepler, and so constitutes no exception to the grand harmonies of the solar system.

In reference to another feature of the position of these orbits, a speculation worthy of notice was recently started by Edward Cooper, Esq., of Markree Castle—a speculation further justified since the addition of many new Asteroids to the list. Mr. Cooper first called attention to the singular fact, in his work on Comets, and he took into his account the larger planets also. With reference to the Asteroids alone, it is this:—Of the fifty-three whose elements are given above, the perihelia of no fewer than forty lie within the semicircle from 0° to 180° , or on its verges; and within the same space are found the longitudes of the ascending nodes of forty-three. The quadrant from 0° to 90° , contains the perihelia of twenty-seven. There can be no doubt that there is a singular speciality here: the laws of probability are utterly against the casualty or indifference of such a distribution. Mr. Cooper is far from inclined to push conjecture too far: he modestly concludes thus:—"After all it may be accidental, as consistently with the laws of planetary motion, such a congregation of perihelia or nodes may occur at periods exceedingly remote."

Notwithstanding the uncertainty in which we are, as to the possible number of these planetoids, some definite light reaches us, from physical astronomy, on the question as to their total mass. In the case of a single planet of the ordinary size, between Mars and Jupiter, not only would its perturbing influence on the nearer orbs be felt, but that influence could be exactly calculated, and traced in all its relations, in the irregularities impressed by it, on their orbits and motions. These small masses must exercise a similar influence; although, from their diffusion through the

sky—the one, on this account, often compensating the action of the other—it is much more difficult, and might even appear impracticable, to deal with the problem. It is, however, only what are termed the *periodical irregularities* (see PERTURBATIONS) that would be compensated in this way. The *secular* variations, on the contrary, do not depend on the relative positions of the disturbed and disturbing bodies. There is, for instance, a secular motion of the perihelion belonging to this latter class. The perihelion alike of Mars and the Earth must be subjected to a perturbation depending on the total mass of these planetoids, their mean distances from the Sun, and the eccentricity of the orbit of the disturbed planet. Owing to the larger eccentricity of Mars, as well as the position of its perihelion, in reference to the mean direction of the perihelia of the discovered Asteroids (which lie almost all in the same semi-circumference of the heavens), that planet is much better fitted than the Earth to be the instrument of such an investigation. Looking at the subject in this point of view, M. Leverrier has lately shown that if the total mass of these planets reached equality with the mass of the Earth, the perihelion of Mars would have been disturbed by them to the extent of *eleven seconds* in a *century*. Now, although the orbit of Mars, and its history during the recent century, cannot be said to be determined with an ultimate rigour, it is safe to conclude that there is not an undiscovered error of this sort, to a *fourth* of the previous amount. From which it would appear that the *sum total of the matter constituting the small planets lying between the mean distances of 2.2 and 3.19 from the Sun, cannot greatly, if at all, overpass one-fourth of the mass of the Earth*. This restricted mass, however, is very considerable, being upwards of twenty times greater than the mass of our Moon; and it doubtless includes within it, multitudes of Asteroids not yet discerned by the telescope.

The contemplation of this very curious group gives rise to singular reflections. How odd the motions of masses of small orbs, with paths so near, that often they must pass within sight, in the celestial spaces—like ships within hail at sea! But whence came they? What means this extraordinary exception to that general law which has constituted the solar system for the most part an orderly arrangement of large orbs moving through spheres far apart from each other, and thus in all things independent? Reflecting on the fact that they occupy the precise place which, in conformity with Bode's Law of the distances, ought to have been filled by a large planet, Olbers threw out the conjecture that these Asteroids may be the fragments of a planet once existing there, but which, in some mighty convulsion, had burst asunder. Nor, perhaps, if one considers the inherence in all planets known to us, of the same disrupting powers which originate volcanoes and moun-

tain masses in the earth, can the conjecture be rejected *à priori* as entirely fanciful. But a fatal dynamical objection remains. If the group are fragments arising from the bursting of one body, they would all, in the course of these revolutions, necessarily tend to return to the period when the primary explosion took place. Laplace, on the other hand, regarded them as indications that a primary or large planet had never been formed there, but that the ring of primary nebulous matter, out of which he imagined every planet to have sprung, had rather resolved itself, in this place, into a multitude of small knots or aggregations.—It cannot escape observation, however, that this group of Asteroids, strange though it may seem, when we compare its individuals with planets like Jupiter, or even the Earth, may not, after all, occupy an isolated place even within our own system. Those showers of meteors that sometimes illumine the heavens, as well as those sparse but startling shooting stars, are probably masses of bodies not unlike the Asteroids, only a step lower down in the progress from large globes to mere dust. And then the *zodiacal light*, is not that still nearer to dust—akin, it may be, to the cometic matter—a thing rare in space? It may, indeed, turn out that our leading planets of the solar system, are only the more visible parts; and that when we know our scheme better, its simplicity will no longer be recognized.

Astræa. One of the small planets between Mars and Jupiter. See ASTEROIDS.

Astrolabe. The name given by the ancients to the instrument by which they measured the angular distances of celestial bodies. It had various forms; but the chief part of it was a graduated circle, around whose centre, as its point, an arm moved carrying *sights*. Rude though the astrolabe was, we must consider it the germ out of which our present Astronomical Circle sprung. See CIRCLE.

Astrology. The *superstition* of the ancient astronomies. The notion on which it rested was environed indeed with something of plausibility, in times when our small world was esteemed the main or central orb of the universe, and the stars gemming the Infinite only lights created for our use. That notion, in its highest form, may best be expressed as follows:—Besides performing their functions as lights, these stars are instruments by which the Creator governs terrestrial events, and their potency may be discerned through their *combinations* and *position* in the sky. It is needless to state, that the postulate, being wrong, every deduction must be erroneous also. The intelligent require no refutation of the postulate; nevertheless, there is an impressive lesson in the fact, that astrological almanacs are still favourites—even with the masses of the people of England. Under our modern civilization, there are very *masses*, over whose heads the discoveries and acquirements of science

den pass. These multitudes live within a sphere of their own, wherein prevail peculiar philosophies as well as peculiar religions. The extraordinary evolution of *Mormonism*, having made patent this astounding fact,—whether is it wise to fulminate against the intellectual and social heresies of *Mormonism*, or, to look deeper, at that ignorance and debasement—accompanied, nevertheless, with the capacities and aspirations of a higher humanity—which are its source?

Astronomical Signs. See SIGNS, ASTRONOMICAL.

Astronomy. The science whose object it is to discern facts and laws concerning the distribution, motions, and nature of the Heavenly Bodies. Its origin is in far antiquity: the shepherd Chaldeans connected, very early, the presence of certain constellations in the midnight sky, with the return of the seasons. We shall shortly distinguish here, the chief steps of its progress. Of these, the first, was that important one which led to the separation of the planets—as wandering orbs—from the fixed stars. This was accomplished in remote times; and in Greece theories arose, with a view to take account of the motions of the planets. These theories were perfected by the Alexandrian astronomers. Resting on the notion that the apparent motions of the planets are *real* motions, or, what is the same thing, that the earth is at rest, and in the centre of all the motions of the universe, the Greeks and Alexandrians reared a complex but most ingenious system, whose authority lasted until the times of Copernicus. Neither in these early days were the apparent motions of the system of the fixed stars overlooked: it is one claim of Hipparchus to immortal honour, that he discovered that great apparent motion of the celestial vault, which we designate as the *precession of the equinoxes*. (Compare PRECESSION). As we descend in astronomical history, not only does the distinction between planets and fixed stars become broader, but inroads are being made into each sphere, more and more successful as years pass on. It will suffice, in this general article, that we refer to *heads under which*, in this Dictionary, minute information, occupying as great space as we can devote to it, will be found.

(1.) *The Solar System.*—The discoveries of Copernicus revealed the cardinal fact, that the earth is merely one planet, rolling with others, and the sun. Several questions immediately arose, *viz. first*, What is the character of the orbits through which these planets move? A question answered by the observations of Tycho Brahe, and the Laws of Kepler. (Compare KEPLER'S LAWS). Next came the inquiry, according to what mechanical or dynamical laws do these bodies move? what new forces do their motions reveal? A question answered by our immortal countryman, Sir Isaac Newton, and his great successors. (Compare ATTRACTION,

FORCE, GRAVITATION, LUNAR THEORY). The *physical characteristics* of the several constituents of the solar system next attract attention. All that has been ascertained on this subject is exposed under SOLAR SYSTEM, and under the special heads of the names of the different planets. To which must be added ASTEROIDS, COMETS, METEORS.

(2.) *The Fixed Stars.*—That great and unfathomable company of orbs which we name the *fixed stars*—orbs of the class of our sun, and round each of which systems of planets probably revolve—interest us in various ways. First, as to their *distance* and *distribution*, see CONSTELLATION, PARALLAX, NEBULÆ. Secondly, as to their physical aspects, compare TWINKLING, FRAUENHOFER'S LINES. Thirdly, as to their *apparent motion*, see PRECESSION, NUTATION, and TRANSLATION OF THE SUN. Fourthly, as to their *real motion*, see STARS MULTIPLE, and STARS, PROPER MOTIONS OF.

(3.) The third important division of astronomy may be termed the *Instrumental*. It refers to the manner by which discovery of facts is now successfully conducted. Information on this head will be found principally under CIRCLE, EQUATORIAL, TELESCOPE, TRANSIT INSTRUMENT. Minor points are referred to under ALTITUDE and AZIMUTH INSTRUMENT, COLLIMATION, ERRORS, &c.

(4.) *Practical Astronomy*, in its narrow sense, will be discussed, in so far as we can discuss it in this Dictionary, under CHRONOMETER, LATITUDE, LONGITUDE, NAVIGATION, SEXTANT, TIME, &c. &c.

The best modern work on astronomy is that by Delambre—the *Histoire* and the *Traité*, in nine quarto volumes. Also, Sir John Herschel's *Outlines*.

Asymptote. A straight line which a curve continually approaches without ever being able to meet it, is called an asymptote. The possibility of this, not seen often at first, will be readily demonstrated in this way. Suppose the curve to be at first distant by $\frac{1}{2}$ foot from the line, and suppose that in the next foot it goes $\frac{1}{2}$ of a foot nearer it, in the next, $\frac{1}{4}$ of a foot, in the next, $\frac{1}{8}$, and so on. If putting all these sums together they will never, however far we carry them, come to make up one-half foot, it is manifest that the curve will never meet the line. The sum of the geometrical series $\frac{1}{2} + \frac{1}{4} + \frac{1}{8}$, &c., when carried on to infinity, is equal to $\frac{1}{2}$, but only then. If we take any finite number we stop short of this, and the curve has not at that point been yet cut by the line. As this holds with any finite number of terms, the curve never reaches the line, but constantly approaches. Each advance is accompanied by an approach, but each approach becomes smaller and smaller. Two curves which have both the same asymptote, and which do not cut one another, are called also asymptotes, by an

ATM

extension of the term. It is only in practice applied to a straight line. There are curves like the circle which evidently cannot have asymptotes. There are others, like the parabola, infinitely extended, which have not. The hyperbola is the commonest instance of a curve with an asymptote.

The term is derived from the Greek, and signifies *not falling together*.

Atmometer, (*ἀτμός*, vapour; *μέτρον*, a measure). An instrument intended to measure the quantity of water evaporated in given circumstances. The simplest atmometer is obtained by exposing a vessel filled with water to the atmosphere, in circumstances as little liable to disturbance during the process as possible. The water is weighed before and after evaporation, and the difference of weights shows us the quantity of water evaporated. A multitude of circumstances, however, such as the dryness of the soil, its nature, the influence of plants upon it, &c., cause the evaporation to proceed more or less rapidly at the surface of the earth, and no atmometer has yet been constructed which serves very well, even at heights above the surface. Belloni, Leslie, Anderson, and others, have described various instruments, in none of which, however, can we place great confidence.

Atmosphere:—the gaseous envelope of any celestial Orb. The term is restricted here, however, to the envelope of the Earth. The discussion of the structure, extent, and habits of our Atmosphere would spread out over almost the whole domain of meteorology: we shall occupy the present essay with considerations of the main portion only, of this important division of physical research,—referring for details to specific articles.

(1.) *Atmosphere, Constitution of*.—Our atmosphere is the recipient of all the vapours and gases exhaled and evolved in the laboratory of the earth; but it may be separated into two portions, closely intermingled, although widely distinct in their character and action, viz.:—I. The smallest, but not the least important section of our compound atmosphere, is its **VAPOROUS** portion,—consisting mainly of an envelope of **AQUEOUS VAPOUR**, interspersed through the other section of it. This important constituent varies in weight from .0033 to .0166 of the entire weight of the atmosphere; but, although it is thus comparatively trifling in quantity, it is an essential element of our aerial envelope, giving rise to many of its leading phenomena and changes, as will be seen below as well as under such articles as **RAIN**, **CLOUD**, **MIST**, **HYGROMETRY**, &c.—II. The **PERMANENTLY ELASTIC** atmosphere; or that large portion of it whose elements are not *condensable* under ordinary variations of temperature and pressure. The three leading permanently elastic gases found in this portion of the atmosphere are *Oxygen*, *Nitrogen*, and *Carbonic Acid Gas*; although there are everywhere distinct traces of *Nitric Acid Gas*, *Ammonia*, *Iodine*, and pure *Hydrogen*. The two elastic fluids first mentioned

ATM

make up the mass of the atmosphere, being found in the proportion of 20.9 volumes of *Oxygen* to 79.1 of *Nitrogen* or *Azot*; while *Carbonic Acid Gas*, the element next in importance, is present only in the low and variable proportion of from .01 to .005. The proportions of these permanently elastic elements, do not in general perceptibly vary with localities; nevertheless, the recent delicate eudiometrical researches of Regnault warn us that this proposition must not be taken as of the last exactitude. The quantity of the important element *oxygen* seems to alter from 20 to 21 *per cent.*—variations referrible to *locality* partly, but also to *circumstance*. For instance, on the invasion of cholera on the Ganges, near Calcutta, in March, 1849, the proportion of oxygen had descended to 20.39. It is horrible even to look at analysis of the air in close and filthy places in our great cities, in the immediate proximity of many crowded dwelling-houses. The following is such an analysis from a confined wynd in Paris. No doubt multitudes of similar ones might be produced from corresponding districts in this country:—

Oxygen,.....	18.79
Azot,.....	81.24
Carb. Acid,.....	2.01
Sulph. Hyd.,.....	2.99

To breathe air so mephitic is to expose one's self to certain death.—We shall proceed to explain, in the order best suited to clearness, the habitudes of this our *Composite Atmosphere*.

(2.) *Atmosphere, the Composite;—Weight, and general Representation of; Variations in the Weight of, according to Locality, Season, and Hour of the Day*.—The determination of the prime physical fact regarding our atmosphere—viz., its weight—we owe to an invaluable instrument, the **BAROMETER**. The action and management of this instrument are explained under **BAROMETER**; suffice it here, that the *corrected* height of the mercurial column represents the height of an envelope of mercury, at the temperature of 32°, which would equal in *weight*, the entire aerial envelope of the earth. In so far as this element goes, our actual atmosphere might be supplanted by a liquid mercurial ocean of the average depth of 29.97 inches: and it will sometimes assist our readers' ability to conceive the changes befalling the atmosphere as it is, if he accustom himself to realize this substitution.—It appears, from observation, that the height of this mercurial atmosphere is not the same in all latitudes, nor in any locality at all seasons, or at all hours of the day. Some of the facts touching on this subject are explicable by theory, others not so as yet.—I. Reckoning from the same level—viz., the sea shore,—the heights of our supposititious atmosphere are found to vary with the *latitude*, according to an empirical law, of whose physical significance we cannot at present give sure account. At the equator and its neighbour-

ATM

had the average height is 29.84 inches. At latitude 10° the pressure or height begins to increase visibly; augmenting on towards latitude 30° or 40°, where it seems to reach its maximum, being there 30.08 inches. Beyond this zone the mean height of the mercurial envelope diminishes, descending in the arctic regions to 29.76 inches. According to some observations, it would appear that the pressure once more increases, on nearer approach to the pole. The details on which these conclusions rest have been collected and presented in an instructive table by MM. Schow and Poggendorf. As to the theory of such variations, nothing satisfactory can at present be hazarded. The latitude of maximum pressure certainly corresponds nearly with the polar limit of the TRADE WINDS (q. v.) This subject is further complicated by a suspicion, if not an established fact, that the mean pressure of the atmosphere varies with the longitude also. The first and great question, evidently, is the construction of a full system of what are called *isobaric lines*, or lines of equal pressure, over all the surface of the globe.

—II. The weight or pressure of the entire atmosphere, varies also over every locality with the seasons of the year. The amount of the variation changes with the locality, and, in so far as observation has yet gone, lies between .178 of an inch off the height of mercury, and .074. There is a distinct connection everywhere with the seasons, although this is at first sight somewhat complex. On an average, the pressure is less in summer than in winter. But a double period is observable. Beginning with its maximum in winter, the pressure diminishes until the equinox; it then increases in summer, never however reaching the winter mean. A second minimum occurs in autumn, after which the curve gradually ascends until it attains the winter or absolute maximum. The following, for instance, is the curve for Berlin, drawn from a meteorological table extending over a greater length of time than any other within reach:—

THE CAUSE OF THESE OSCILLATIONS IS APPARENTLY THE TEMPERATURE OF A COLUMN OF AIR

ATM

be augmented, the height of that column necessarily increases; so that the heated column may be conceived to overflow at its top, and therefore, as a whole, to become lighter. On this account the pressure should everywhere be less in summer than in winter; as we have said it is, in the main. Why these anomalies—several maxima and minima—exist, or why the curve of pressure does not exactly follow the curve of temperature, will appear in our next section; wherein we shall consider, apart, the habitudes of the aqueous and of the permanently elastic atmospheres.—III. The weight of the atmosphere over every locality varies also, according to a regular law, according to the hour of the day. Although plainly connected with temperature, this variation, like the former one, also presents anomalies. In the course of every twenty-four hours, the Barometer presents us with two maxima and two minima; recognizable in every set of observations that have been continued long enough to enable us to get rid of anomalies, or of the effect of irregular fluctuations. The hours at which these crises take place—or, as they are called, the *tropical hours*—vary somewhat with the place of observation; generally speaking, however, they may be taken to be as follows, in the northern hemisphere:—

Minimum of morning,....	8 h. 45 min. A.M.
Maximum —	9 h. 37 min. A.M.
Minimum of evening,....	4 h. 5 min. P.M.
Maximum —	10 h. 11 min. P.M.

These tropical hours vary also in each place with the season; during winter they are nearer mid-day on the whole, by about two hours, arriving later in the morning and sooner in the evening.—Another feature of this diurnal oscillation is remarkable. Its amplitude or amount—which is best represented by the difference between the mean of the two minima and the mean of the two maxima—varies with the latitude of the place, the season of the year, and the height of the place above the level of the sea. It is greatest at the equator, diminishing as we approach the polar circle, where it becomes almost insensible. In winter, in all localities, it reaches its yearly minimum, rising to a maximum in summer. With the height of the place, again, these variations change in a complex way; the hours of maxima and minima becoming reversed. But as such changes will be better understood when referred to their causes, we shall postpone especial notice of them until next section.—It is of the last importance to the study of all the relations of the atmosphere, that the mean daily height of the barometer be determined at every place of observation; and, as the foregoing variations seem to render this a little difficult, the mode of accomplishing it may be specified here. If the height in question be measured every hour, or very frequently and at regular intervals, during the twenty-four hours,—the sum of the readings,

divided by the number of the times of observation, will give the daily mean. That same mean, however, may be obtained approximately by taking observations of the morning maximum and afternoon minimum. It is better, however, to take either of the following three sets, first at 6 A.M., 2 P.M., and 10 P.M.; or, secondly, 7 A.M., 2 P.M., and 9 P.M. The barometer attains its own mean height between mid-day and one o'clock—the moment varying according to the season.—IV. The weight of the atmosphere over any locality is likewise subject to other and apparently irregular fluctuations. These depend on *motions* within our aerial envelope itself, and will be treated in a subsequent section, as well as under RAIN, WINDS.

(8.) *Atmosphere, Causes of the Changes of Weight of. Influence of the Habitudes of its Constituents.*—We shall not attempt at present to explain the causes of those *permanent* irregularities in the weight of the atmosphere, which depend simply on the *latitude*, and apparently also the *longitude*, of the place. But the fluctuations adverted to in II. and III. paragraphs of the foregoing section can readily be accounted for. In the case of a permanently elastic atmosphere, a proposition, already hinted at, would be absolutely true:—*When the barometer falls in a country, it is because the temperature of the country is higher than that of the neighbouring countries, whether because it is heated directly, or because these countries are cooled; on the contrary, the rise of the barometer proves that this country becomes colder than those which surround it.* A proposition flowing out of one general and simple consideration, viz.:—In an atmosphere in *equilibrium* as to temperature, all its columns, from base to extreme surface, would at every locality be of the same height and weight. If one column be heated, it will, as has been said, expand and *flow over the others*, or, it will *lose in weight*. On the contrary, if a column is cooled, it will contract in volume; and the neighbouring columns will flow into it, and *augment its weight*. Taking this for our ground then, we would expect, that as a country becomes heated, whether during the course of the seasons, or according to the hours of the day, the barometer should fall there, and *vice versa*; in other words, the *maximum* of the barometer should occur everywhere, on an average, at *mid-winter*, and its *minimum* at *mid-summer*; while two opposite crises should occur in its diurnal course, at the hours of greatest daily cold and greatest daily heat. Now, although in the facts already mentioned there is a general correspondence with these laws, we detect apparent anomalies likewise. For instance, why have we that irregularity in the curve of the barometer during the season? whence the apparent *minima* in spring and autumn, and that comparative ascent in summer? And although, as day proceeds, the mercury falls between the periods of mean temperature—viz., 9 or 10 in the morning,

and 9 or 10 in the evening—and an hour close on the hour of *maximum daily heat*; whence the singular *minimum* of an hour of the night corresponding so closely with the hour of *greatest cold*? By consideration of the different habitudes of the two *constituents* of our compound atmosphere, these apparent anomalies are easily explained. As already stated, we have a *vaporous* mass mixed with our permanently elastic envelope, comparatively small in amount certainly, but quite efficient, through its extreme sensitiveness to changes of heat, to impress *anomalies*. Now the weight of the vaporous atmosphere must evidently increase with the heat of the *season* and the *hour of the day*, and *vice versa*. Its relations to the barometer and thermometer are therefore the *inverse* of that of the permanently elastic envelope; and *out of this contradiction* the enumerated anomalies spring. Fortunately the two atmospheres can be separated. By the instruments of hygrometry (see HYGROMETRY, PSYCHROMETRY), the weight of the vaporous atmosphere is measured *by itself*; and by subtracting this weight from the total weight of the air, we obtain the weight of the dry mass of air surrounding us. Separating, then, these two counteracting influences, and attributing to each, its effect on the barometer, we reach the following conclusions:—I. When the effects due to the vaporous atmosphere are deducted, and we have the weight of the dry or permanently elastic envelope alone, the minima of spring and autumn disappear, and the heights of the barometer are inversely as the heights of the thermometer; the one *maximum* of the year occurring in the *depth of winter*, and the one *minimum* at the *hottest period of summer*. The declension of the weight of the composite atmosphere in spring and autumn is due to this:—In spring the pressure of the dry air rapidly diminishes, while there is no compensating or corresponding increase in the amount of vapour. This last increases rapidly towards the height of summer, compensating for and counteracting, in so far, the continued diminution of the weight of the dry air; and in autumn the aqueous vapour rapidly precipitates, while the weight of the dry air augments only slowly. Exactly, too, in proportion as the seasons differ from each other at any place—i. e., according to the difference between mean winter and mean summer temperature—is the difference between the winter *maximum* and summer *minimum*.—II. The diurnal oscillations of the barometer or of the weight of the atmosphere, although somewhat difficult to explain in all places, evidently originate in this same complex character of our envelope. M. Dove, of Berlin, first proposed a separation of the effects of the two atmospheres, as the key to these irregularities; and the following are his general results:—Take away the effect or weight of the vaporous atmosphere, and the oscillations are reduced to one single curve; viz., from a *maximum* some time after midnight, or the hour of greatest

ATM

add. to a minimum at the hour of greatest heat; the crises in the morning and evening disappear. The midnight maximum of dry air becomes the minimum of the composite atmosphere, because of the remarkable abstraction of, or condensation of vapour, necessarily occurring at this diurnal period. There is a morning maximum again, because of the rapid ascent of vapour as the temperature of the day augments. About three or four in the afternoon, the great descent of the weight of the dry air, counteracts the augmented weight of vapour, and constitutes a minimum; while the diminution of vapour towards evening, overcompensated by the increase of weight of the dry air, occasions an evening maximum. The theory now given, may be carried out so far as to account for the varying amplitudes of the diurnal oscillations, according to latitude; so that these apparently difficult movements of the barometer, are really nothing more than one regular feature of the climate of a place.

(4.) *Atmosphere, the Habitudes of a Vertical Column of.*—It is now necessary to consider our aerial envelope in reference to another of its dimensions, viz., its height or depth, and the phenomena belonging to its various strata—arranged according to their altitudes. As explained in a previous article (ALTITUDES, MEASUREMENT OF), the densities of the various strata of air, or what is the same thing, the weight of the masses incumbent on them, decrease in geometrical progression as their height above the surface of the earth increase in arithmetical progression; which theoretical principle, coupled with facts deduced from observation, enables us to construct as approximately accurate, the following table:—

Height in Miles.	No. of Times Rarer.
0	1
3½	2
7	4
14	16
21	64
28	256
35	1024
42	4096
49	16384
56	65536
&c.	&c.

It is evident that at such a rate of diminution of density the atmosphere may virtually be said to have a physical limit not far removed from us: did it extend as high above us, as London is distant from the city in which we write (Glasgow), one cubic inch of the air we breathe, would be expanded so vastly that it would fill a sphere equal in diameter to the orbit of Saturn! But the outer boundary of the atmosphere is far less remote; one can scarcely conceive it extending higher than from 100 to 150 miles. There are two very important considerations intimately mixed with this rapid declension of the density of

ATM

a vertical column of air.—I. The temperature of the atmosphere diminishes as it grows rarer, or as we ascend in it. The exact relation of this decrease of temperature and decrease of density is perhaps not accurately established; and it is plain that it must be seriously affected by the diverse winds prevailing in diverse parts of the earth, and other circumstances. Nevertheless, it may be stated that in our northern climates the diminution is not far from 1° for 270 feet of perpendicular ascent. Or more accurately, a general formula may be given in the following terms. Taking 85° as the mean temperature of the surface of the earth at the equator, and 58° the mean temperature at latitude 45°, we have for any other latitude ϕ , the mean temperature t , from this equation—

$$t = 58^\circ + (85^\circ - 58^\circ) \cdot \cos 2\phi$$

or

$$t = 58^\circ + 27^\circ \cdot \cos 2\phi$$

and if the place is h feet above the surface of the ground, or n times 270 feet,

$$t = 58^\circ + 27 \cos 2\phi - n$$

On ascending into the atmosphere, at every latitude, a point or altitude will always be reached at which it rather freezes than thaws; a point named the point or limit of perpetual congelation. This point is found with a general accuracy by the equation

$$82^\circ = 58^\circ + 27 \cos 2\phi - n$$

or

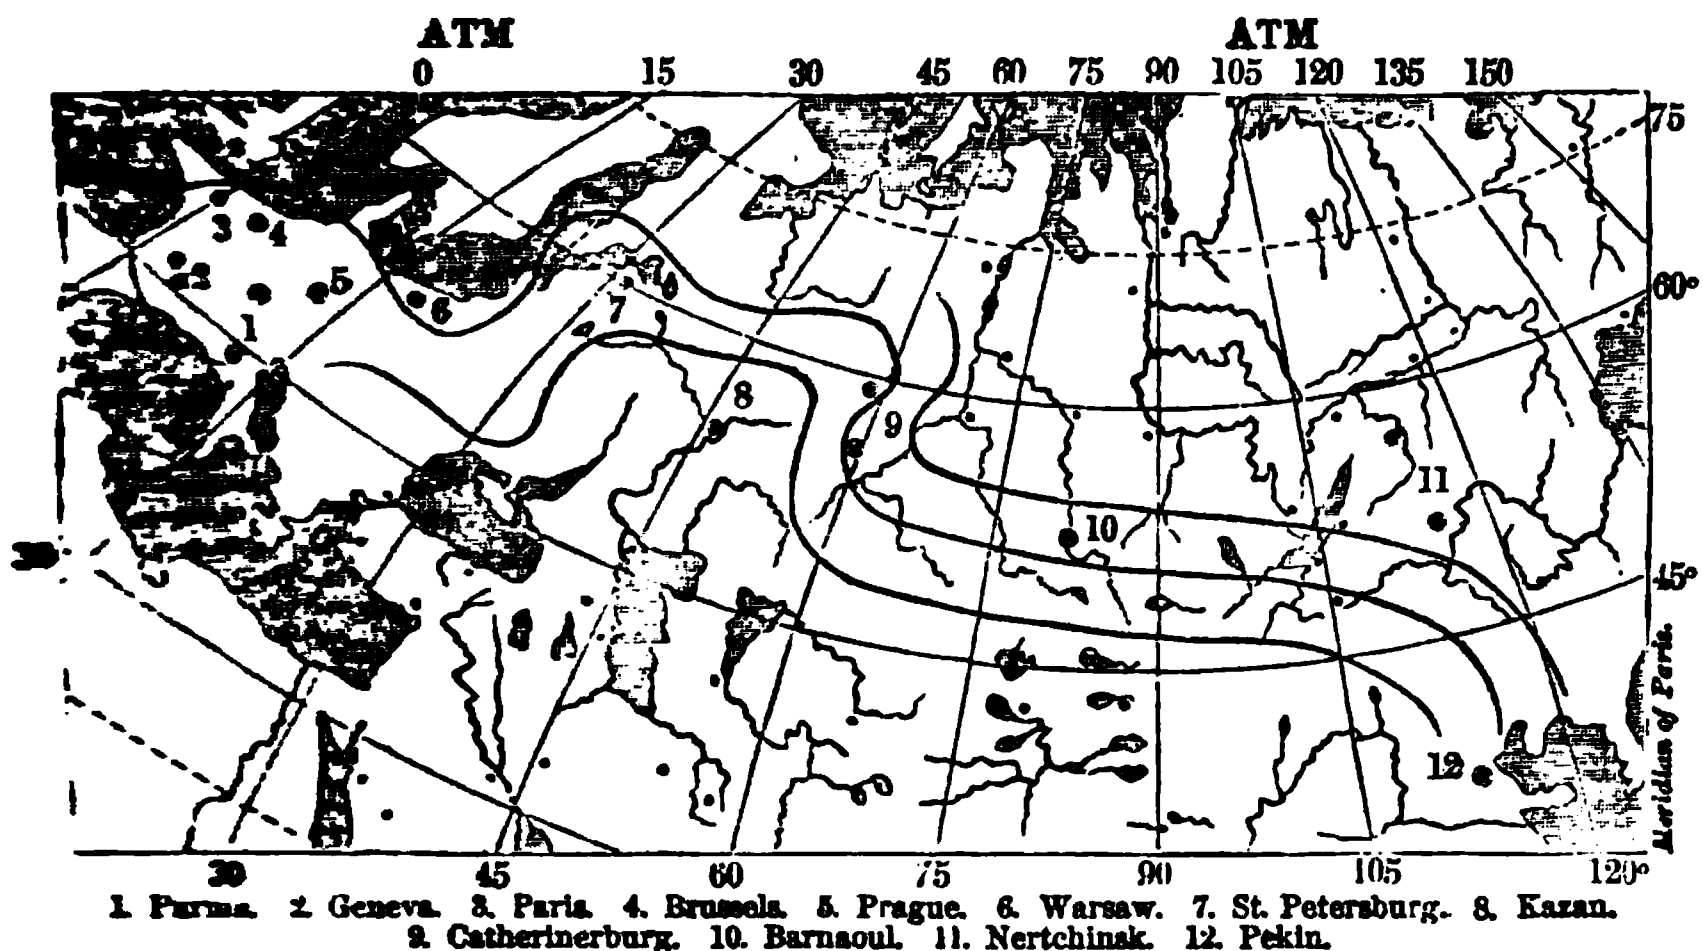

$$n = 26 + 27 \cos 2\phi$$

a formula which would give 14000 feet as the height of perpetual congelation at the equator. The actual height is greater than this; but the formula tolerably well represents the average elevation of the line at the various latitudes. No general formula, however, is applicable, unless the limit of accuracy be regarded as very wide, inasmuch as the height of perpetual snow in any country whatever, depends during any course of years, on elements having little connection with the latitude, such as the temperature of the plains or plateaux above which the snows fall, the degree of the heat and the duration of the summers, the quantity of snow falling during winter, the prevailing direction of the winds, the more or less continental character of the country, the dryness and transparency of the atmosphere, the escarpments of the mountain summits, and the masses of neighbouring snows. In the immediate proximity of this line of congelation, lying closely below it, is the region of the glaciers, those immense masses of moving snow and ice which have performed so important a part in modifying the present surface of our globe. II. This regular diminution of temperature, as we ascend in the atmosphere, induces very important effects on the vaporous portion of our envelope.

It is easy to see, in the first place, that since this vaporous portion, however small its relative quantity or weight, plays the remarkable part assigned to it above, in the production of the barometric oscillations at the surface of the earth, we should here expect a key to changes in the law of these oscillations, according to the elevations at which we observe them. The vaporous atmosphere diminishes in weight as we ascend, much more rapidly than the dry air, and its influence accordingly becomes less and less felt. But of much more importance is this,—the vaporous atmosphere is constrained to adjust itself to the temperatures of the dry atmosphere; and as these temperatures are not what its different strata would naturally assume, it must be regarded as placed by its associate in a *condition of restraint*. Out of this *restraint* almost all the phenomena of *hydrometeors* may be said to spring; and these again react on the dry atmosphere and produce in it remarkable changes. The topics now referred to, will be fully discussed elsewhere; especially in the articles on *HYGROMETRY*, *HYDROMETEORS*, and *WINDS* (q. v.)

(5.) *Atmosphere; Irregular Oscillations of, Weight of, Motions of.*—Besides the periodic oscillations now mentioned, the weight of the atmosphere over every locality is subject to changes, recurring indeed, but whose periods are not fixed,—originating in more complex causes. It cannot have failed to be observed, that, through effect of what has been explained, our aerial envelope must be in a condition of unceasing motion. That inequality of heat which belongs to the surface of our globe (*CLIMATE*) necessarily affects variously the columns of air superincumbent on the surface; these cease to balance each other in a state of rest; and interchanges of currents, with a view to the re-establishment of equilibrium, are the consequence. To facilitate an accurate apprehension of the character and effect of such motions, it is needful to distinguish carefully the two quite different ways in which any fluid,—whether liquid or permanently elastic,—can be agitated. These two ways are as follows: *first*, by effect of a transmission of its particles from one place to another at a greater or less rapid rate, as, for instance, in the case of *currents* of water or rivers, or aerial *winds* or *gales*; and *secondly*, by the mere transmission of *motion* or of *oscillations*, as in the case of the propagation of vibrations along an outstretched string. Of this latter sort are the tidal waves of the ocean, which, every observer knows, do not *transport a floating body on their surface*, that body remaining comparatively fixed, or only rising from the trough to the crest of the waves, and *vice versa*, as the waves themselves roll by; and of this sort also are those great atmospheric oscillations now termed *atmospheric waves*. The phenomena and influences of these two descriptions of motion are manifold; we shall give a brief account of them separately.—*I. Atmospheric waves.*—Every close

observer of barometric changes must have noticed the remarkable fact, that, irrespective of diurnal and seasonal changes, there appears everywhere, a flow more or less regular, of what may be termed barometric *maxima and minima*, unaccompanied by winds, or at all events having no visible relation to winds: first, there occurs a minimum of pressure, then the pressure gradually rises until it attains a maximum, from which it again returns to a new minimum. These successions are evidently no repetition of one phenomenon, because the distance of time between the two minima, and the difference of pressure between the maximum and minimum, are not the same on the recurrence of the change; they are rather a series of individual phenomena, much of the same kind. It is observed too, that such changes at one place are attended by corresponding changes at many other places distant as well as near, so that the entire occurrence may be represented by the supposition, that a great atmospheric wave is being propagated across these localities,—the period of *maximum* pressure being the moment of the transit of the *crest* of the wave, while the preceding and succeeding *minima* indicate the passage of its trough. The distance from *minimum* to *minimum* would, under this view, indicate the *breadth* of the oscillation or wave, and the difference between the *maximum* and *minimum* pressure, its *amplitude*. The character and progress of these waves have not been closely studied until recently, and our knowledge of them is still very imperfect. By the labours, however, chiefly of Mr. Birt, who has wrought most effectively under the encouragement of the *British Association*, certain important results have been established. The Atmosphere it appears is always agitated by such waves; and there appear to be many systems of them,—one system often meeting with another, and occasioning curious and complicated *knots* and lines of pressure. The extent of a main wave is very great: of which the chart at the top of next page is highly illustrative. It traces the progress of a minimum for three successive days, over that vast stretch of country from *Paris* to *Pekin*, and indicates the velocity of its march. The bendings of these curves are very curious, being caused chiefly by the different velocities with which the waves are propagated over different regions. The lap round the Alps is especially noticeable. Mr. Birt has gone into much greater detail than we can follow here; he has even sketched the shape or section of several important waves in his various reports.—The various causes of these oscillations cannot of course be accurately ascertained, until the facts concerning them are known over the greater part of the earth. But something—although not the whole—is apparently due to disturbances occurring in the polar regions, through the sinking of the upper equinoctial currents of air (see *WINDS*), and the departure southward of the colder polar currents. If this interchange took

Ordinary Propagation of Atmospheric Waves, with lines for June, 1841.

place exactly at the pole, we should have a regular propagation of waves towards the south, extending around the whole earth; but as it does not do so (see TEMPERATURE), there must arise a series of separate waves, stretching out towards the south along *sectors*, whose angles are more or less acute or obtuse, and generally interfering with each other. The following general conclusions, however, may be safely accepted as summing up our present knowledge of the phenomena and progress of these waves. *First*, The atmosphere is constantly traversed by several different systems of waves. These interfere or interlace, and so produce over every locality on the earth, a special condition of atmospheric pressure. *Second*, Amidst all the variations of such movements, there may be always traced a predominating system of waves belonging to and characteristic of the same climate, or large portion of the globe. *Third*, All atmospheric waves, in Europe and Asia, are propagated from north to south, although not with the same velocity; they move more rapidly in central Europe and in Asia, than they do in Russia and the countries around the Ural (see *Chart*). *Fourth*, Atmospheric waves are propagated with greater facility over the surface of oceans, than across continents. In general the asperities of the globe, especially chains of lofty mountains, diminish their velocity and also impair their intensity or amplitude. *Fifth*, This inequality of velocity on continents, the neighbourhood of the sea, and near mountains, explains the inflexions or sinuosities of the line in the foregoing chart, as well as of all other lines of progress yet known. *Sixth*, The velocity of propagation, as already said, is variable. As an average velocity we may state from eighteen to thirty miles an hour; at the Ural they do not move more rapidly than six miles an hour.

Seventh, The direction and progress of atmospheric waves have no relation to the prevailing winds. It is with them exactly as with waves of sound, which are transmitted in all directions without regard to the winds, although these last sometimes modify both their intensity and velocity.—It scarcely requires to be remarked how importantly the progress and concurrence of these great oscillations must modify atmospheric pressure over every locality. The complete mapping of them is a task very far from being accomplished; nor until after that—though constant observation at vastly more numerous stations—shall have been achieved, would it be reasonable to expect a satisfactory theory of their origin and habitudes. One cannot avoid reflecting, that were the outer shell of our atmosphere self-luminous, these waves and their interlacings would present to a spectator from without, features far from dissimilar to that singularly mottled aspect of the apparent surface of the Sun.—II. The second class of motions characterizing the mass of the atmosphere, is much more noticeable, through the higher and more palpable nature of its effects. Winds, properly so called, are true currents—violent displacements of the aerial particles—just as the water of a river does not oscillate but flow onwards. The mainspring of all such translations has been already indicated, viz:—if one vertical column of air be heated or cooled, a current is necessarily thereby determined towards the heated column or from the cooled one. The physical relations and character of different regions of the earth render this inequality of heating an essential part of its constitution: for instance, the equinoctial columns of the atmosphere must always be warmer than the polar; the air over continents must be warmer in summer and colder in winter than the air over con-

iguous oceans; the air resting over a desert of sand, is always hotter than that which overhangs a region of forest, &c. &c. *Winds* thus arise necessarily; they must exist always; and whatever their complication, they form, as we have said, an essential characteristic of our atmosphere. The subject which has now come before us being one of the most complex and extensive connected with the physical geography of the earth, cannot rightly be discussed as part of another article. We shall give a synoptic view of our knowledge concerning it, under the appropriate head—*WINDS*, to which general head we refer all aerial movements of translation, whether these are local or cosmical, gentle or so violent that they amount to *hurricanes* and *typhoons*,—generically to *storms*. It may be remarked in this place—in reference to much already adverted to—that each wind has, in every separate locality, its peculiar but determinate barometric influence, so that the variability of winds has to be subjoined to those many causes above specified, of variations of Atmospheric pressure. Compare the article just mentioned.

(6.) *Atmosphere, Heat of.*—Some leading facts regarding the heat of the atmosphere have been already spoken of. For the rest compare *TEMPERATURE*.

(7.) *Atmosphere, Optical Phenomena of.*—The Atmosphere acts upon the Ray passing through and into it, in various ways:—It *absorbs*, and therefore *reflects* it partially; it *refracts* it, and thereby evolves very interesting phenomena; it acts by *diffraction* and *interference* in producing curious appearances; and it also *polarizes* the solar beams. We shall do little more in this article than refer to the different heads under which the various aspects and operations just spoken of, are explained in sufficient detail.—I. The *colour* of the air is mainly *blue*; a fact apparent in the blue tint assumed by distant objects—as mountains—seen through it. The explanation usually given is, of course, this:—That the particles of the atmosphere *reflect* blue rays chiefly, and *absorb* or transmit the other rays. But the whole subject of the optical relations of gases, is at present vague and incomplete. It seems likely that a bundle or sheaf of solar rays, passing through large thicknesses of air, gradually loses the blue rays by *diffusion*; hence, perhaps, the circumstance that celestial objects near the horizon appear of the tint complementary to the blue, viz., the *yellow*. This same fact is indicated by the spectrum received from the sun at different altitudes. As the sun's altitude declines, the violet part of the spectrum gradually shrinks in comparative space; at last it disappears altogether, and the spectrum yields only red, orange, yellow, green, and a small portion of blue. The optical properties of aqueous vapour give additional interest to these phenomena. The yellow tints of the sun and moon, seen through clouds, are owing to these properties; hence the common saying, that a red setting sun is a sign of great

humidity. It is, of course, not possible to separate the effects of the humid atmosphere from those of the dry one, or to say exactly what is due to the one and what to the other,—they being always intermingled. The only general conclusion we can reach is that, as with the sea, our aerial envelope belongs to that class of bodies which have two colours—one through effect of reflection, and the other from light transmitted.—Instruments have been devised for measuring the tints of the sky. see *CYANOMETER*, *DIAPHONOMETER*. See, also, *STARS*, *Accidental Colours of*; and *DAWN* and *TWILIGHT*.—II. The atmosphere plays an important part, through its power to *refract* light. Its functions in this respect are fully discussed under *REFRACTION ASTRONOMICAL*; *MIRAGE*; *RAINBOW*; *HALO*; *PARHELION*.—III. To *diffraction* and *interference* we owe the phenomena of *CROWNS* and *ANTHELIA* (compare these articles); and under the head *POLARIZATION* is placed a full explanation of that curious subject, the *polarization of the Atmosphere*.—These references will guide the student to as accurate a knowledge of the several subjects as our limits permit us to offer him.

(8.) *Atmosphere, Electricity of.*—It is well known, and will be explained in detail under appropriate articles in this Dictionary, that when the particles of a body experience any derangement, or undergo any change whatsoever, whether as to their natural position of equilibrium, in their grouping, or in their chemical constitution, there supervenes an immediate separation of a part of what are called the two electricities; or, to speak more rigorously, a certain development of the electrical polar forces. This phenomenon is invariably produced whenever the particles are shaken, or separated by friction, percussion, heat, light, chemical action, &c. Now this same separation of the electricities, or development of the polar forces, appears an essential element of relations between the earth and atmosphere; which two portions of the terrestrial spheroid are, through the influence of causes far from well understood, always in opposite electric states—the latter manifesting the positive force, and the former the negative force.—I. Premising that the instruments used in detecting the existence and variations of atmospheric electricity will be described under *ELECTROSCOPE*, *ELECTROMETER*, and *MULTIPLIER*, we shall first lay down, in due order, the general laws which the facts already accumulated seem to indicate on this curious subject. 1. As already stated, the electricity of the earth is *negative*; that of the atmosphere *positive*: extending to a slight distance from the surface of the earth (a distance varying according to the nature of the soil, but which in the *open country* is from three to five feet), there is a *neutral stratum*, above which the positive polar force manifests itself, increasing in intensity as we ascend. To ascertain the law of this increase were of great importance; and the object has

been sought to be accomplished by aid of *kites*, *captive balloons*, and *arrows* shot to various heights. The practical difficulties of the investigation, however, are very great, nor have any results more precise than the following been yet obtained:—*First*, If an isolated body near the surface of the soil, and previously in communication with the soil, be brought into contact with the electroscope, the gold leaves do not separate or give signs of electrical tension; but if the sky be clear, and the apparatus is carried to a height, the leaves diverge, and indicate positive electricity. *Secondly*, The tension thus indicated increases with the height. *Third*, The action between two bodies showing electric tension, takes place with increased facility, if one or both of them be easily vaporized. There is, therefore, more powerful action between the atmosphere and surfaces of water, than between it and dry surfaces. Vaporization is increased by this action; and vapours in a *vesicular* state are thus diffused through the air, and retain that state so long as their molecules remain in the vesicular state. (See *CLOUDS*). *Fourth*, When the air is dry no electric indications can be obtained, unless through means of very long rods; when it is slightly humid, on the other hand, continuous currents appear, although the rod of the instrument be comparatively short.—2. During serene weather the tension of atmospheric electricity undergoes regular variations, according to the hour of the day and the season. We owe most important knowledge on this subject to Schubler of Stuttgart, Arago of Paris, Quetelet of Brussels, and lately to the meteorological Observatory at Kew. It appears, *first*, that we have everywhere two daily *maxima* and two daily *minima* of tension. At Stuttgart, for instance, there is a *minimum* at *four* in the morning, a *maximum* at *eight*, a second *minimum* at *five* in the afternoon, and a second *maximum* between *eight* and *nine* at night. And, *secondly*, that the *greatest* intensity is in *winter*, and the *least* in *summer*; or, rather, that in serene weather the intensity of atmospheric electricity is in proportion to the increase of *cold*. The cause of these variations is probably the following:—Towards midnight the electricity of the atmosphere ought to be feeble, because the *humidity* of the evening and the first hours of the night must, through its conducting power, have transmitted to the earth a portion of what had previously accumulated in the air; when the sun has risen with its heat, the vapours rise, instead of *falling*; so, all discharge in this way ceases; as the sun's heat increases, and ascends to its maximum, the air gets quite dry, becomes a bad conductor, and thus affects the instruments only slightly; finally, as the sun descends, vapour is precipitated, and for a time transmits electricity very abundantly from above—so that we have *daily two apparent maxima* and two minima.—In the same way the annual variations can be explained. During the heat of summer the air

is dry, and a bad conductor; while in winter the humid air is a good conductor.—It would seem, therefore, that these maxima and minima rather relate to the conductive power of the inferior strata of the atmosphere, than to the absolute tension of atmospheric electricity itself.—II. The foregoing results, imperfect as they are, do not hold except when the sky is clear. The formation of *clouds* originates other electric phenomena, of great complicity, and sometimes of remarkable splendour. The student will consult *CLOUD*, *THUNDER-STORM*, *LIGHTNING*.—III. Certain imposing *meteoric phenomena* are likewise due to the electric state of the atmosphere. See *WATER-SPOUT* and *HAIL-STORM*.—IV. As to the origin of atmospheric electricity, a few words must suffice, nor are these proposed in confident solution of the difficulties of this obscure subject. The inquiry as to the origin of any development of the electric forces is tantamount to this:—What changes are proceeding among molecules of the bodies in connection with which the development takes place? The most evident and extensive change of molecular condition, connected with the relations of the earth and atmosphere, is *evaporation*. It is established by decisive experiments, that during the process of the pure and simple evaporation of water, at the surface of the earth, no palpable electricity is disengaged; the negative electricity of the foam and vapour produced at *jets-d'eau* and cascades being referable to quite another cause: but there is a certain development of the polar forces, during evaporation from *saline masses*. Something of the phenomena in question may also be attributed to those innumerable chemical reactions that occur within organized bodies; although as these reactions take place in very different directions, and the gases that escape are continually touching the surfaces and interior parts of these bodies, it is certain that quantities of developed electricity, must be *immediately recomposed*. Only one other resource remains, viz., *thermo-electricity*. It is well known that the unequal distribution of heat in a heterogeneous metal suffices to separate the electricities; the portions which are most heated taking a negative electricity, and those which are least heated, positive electricity. It is not improbable that we ought to consider the earth and atmosphere under this relation. The higher parts of the atmosphere, because of their rapidly diminishing heat, ought to become more and more positive, while the earth should show an increasing negative intensity downwards to its centre. This explains the fact too, of the greater separation and display of electric forces in the tropic regions; for there the foregoing contrasts are the greatest. The intensity of these phenomena naturally diminishes as we pass towards the temperate zones; and it may be that the polar regions, where the aerial gradation of heat is comparatively inconsiderable, serve as a point of re-union to the polar forces disengaged elsewhere; and it

may be, in so far, on this account, that they are the theatre of the brilliant displays known as the Aurora.

Atmospheres of the Planets. See Appendix.

Attraction. Among the various motions visible in the material universe, there is a large and important class, resembling, in every way, what would take place if one portion of matter drew other portions towards itself; for instance, as with the magnet and a piece of iron: to this class of phenomena the name or term *Attraction* has been assigned. The phenomena in question may be divided into *direct* and *indirect*, or, perhaps, *simple* and *composite*. The *simple* instances of attraction in the universe are countless. Foremost of all, we have the case of *falling bodies*, first scientifically treated by Galileo, which originated the idea that the earth, and perhaps every portion of it, have a significance amid surrounding motions, as if they drew all other matter towards them. This latter extension of the phenomena of terrestrial attraction, was completed by the demonstration by Maskelyne, of the effect of the mountain Schellien on the plummet, and by those curious experiments by Cavendish (since repeated by Mr. Baily and others), which demonstrate that balls, of perfectly *unmagnetic* metal, visibly attract each other. To this same class must be referred direct magnetic attraction, electric attraction, &c. The indirect instances of attraction have the following characteristic. Attraction is not seen in them *purely*: it is inferred as one of the simple or primal constituents of a *composite* phenomenon. For instance, in case of a trajectory or projectile, the attraction of the earth enters as an element; for when we disengage, from the motion of the projectile the effect of the *horizontal* impulse given it, we find, alike in its ascent and descent, the precise phenomena of falling bodies. Again, the planets do not fall to the sun, as a stone does to the earth; but if we disengage from their curvilinear motion the effects of a primal impulse onward, we also detect as a *residuum*, this tendency to fall towards the sun, as if they were drawn towards him. In the same way all chemical phenomena are conceived to indicate attractions indirectly; so that it has come to be held as an assumption, which may be accounted general in physical inquiries, or, in other words, a *physical axiom*, that all matter tends to attract or draw towards it other matter, unless in the case of opposite *polarities* (see POLAR FORCES). Further speculative views on this subject are given under the article BOSCOVICH. There are two very distinct and disparate lines of thought and inquiry regarding these phenomena of *attraction*. 1. The investigation of the *laws* or the *order* of those motions to which we apply the epithet *attraction*. In regard to *falling bodies*, this was at once begun and accomplished by Galileo. Newton finally

disposed of the important question in reference to that veiled attraction towards the sun, which is indicated by *planetary orbit*, and *velocities*: others have wrought, and are working, in the same field, as to electric, magnetic, and chemical, and other physical attractions. 2. It is quite otherwise with inquiries as to the *physical cause* of the phenomenon named *attraction*; of this, physical science can never know anything. It may discern relations connecting the various attractions, and thus, it may be, ultimately assimilate them, or discover some simple law that comprehends all their diversities; but the material world can never reveal anything but *sequences*, and the order of *sequences*; so that the inquiry as to the *efficient cause* of such phenomena is beyond reach of physical inquiry. The frequent misconceptions as to the physical significance of the word *attraction*, and the mass of useless speculation thereon built, would have been avoided, had attention been paid to the important truth now indicated; nor can we altogether exempt from censure those speculations by Laplace, which seemed to this prince of mathematicians but very indifferent metaphysician, to intimate almost an *à priori* necessity for the *law of gravitation* of Newton. See *Système du Monde*.

Atwood's Machine. Perhaps no questions in mechanics are more interesting than those concerning the fall of bodies. They were, however, for a long time the subject of but very slight and inefficient experiments. Bodies fall in so short a time through so considerable a space, that it was found impossible to get to elevations fitted in other ways for the purposes of experiment, sufficient to let us observe them easily. Besides, the resistance of the air, though at the commencement of a body's fall very slight, becomes yet considerable as its velocity increases. The machine of Atwood proposes to reduce the velocity of falling bodies, and so to enable us to observe their laws, by giving us time for experimenting, and by rendering the resistance of the air comparatively insignificant. It accomplishes this object thus:—A string, to which two equal weights are attached at the two ends, passes over a pulley, and remains in equilibrium. A very small weight (small compared with either of the equal weights) is then added at one end, and the string at that end commences to descend. It is evident that the force which gravity exerts upon the descending equal weight is exactly balanced by that upon the ascending. The only force acting, therefore, upon the weights is the force of gravity pulling the smaller weight down. This force is used to produce an equal motion upon the three weights together; and we have thus, calling *g* the force of gravity operating on these

three weights, if left free, a force = $\frac{g n}{2 m + n}$, where *m* represents either of the equal, and *n*

the smaller weight. This force will be equal to

$$g \frac{1}{1 + \frac{2m}{n}}, \text{ where } \frac{2m}{n} \text{ may be made as large}$$

as we choose, by sufficiently increasing m and diminishing n , and where, consequently, the proportion of the force acting upon the mass, to the natural force of gravity upon it, may be as small as we choose. The velocity will be proportionally small, and the times of describing measurable spaces will be easily measured also. By the help of this instrument we may establish, experimentally, the following laws:—That the spaces described by a body acted upon by a constant force are proportional to the squares of the times, and that the velocities acquired by the body are proportional to the times. This last law will be observed, if, after finding to what points the body reaches in the successive seconds, rings be placed, which shall permit the larger body to pass through, and which will detain the smaller. The motion will continue with the velocity impressed at the moment of this change, and without increase or sensible diminution. Practically, a clock beating seconds is attached to the machine, and a very delicate machinery is employed in rendering the friction of the cord upon the pulleys as slight as possible. This does not, however, interfere in the least with the principle of the apparatus.

August. The eighth month of our year. It was originally called *Sextilis*, or the sixth month, from the position that it held in the year of *Romulus*. It received its present name in honour of the victories of the emperor Augustus, 8 B.C.

Auriga. A northern constellation.

Aurora Borealis, or, rather, the **POLAR AURORA**,—that which appears in the Arctic regions being named *Borealis*, while the Aurora of the southern pole is the *Australis*. This singular and most beautiful phenomenon consists of *swallow lights variously coloured*, which dart, at certain seasons, from all parts of the horizon in polar countries; and it is usually announced and accompanied by great magnetic perturbations, indicated by startings of the needle. In our regions of the earth, the Aurora appears at first usually like a dingy fog, in and somewhat above the northern horizon, and generally rather brighter towards the west. By and by this dim mass takes on the form of a circular segment, resting, at each end, on the horizon; the higher part of it being surrounded by a white light, sometimes resolving itself into one or two distinct luminous arcs. Then begin these well-known beams and shoots of diverse colours, originating in the obscure segment, which they break up into bright patches, as if they threw the whole of it into a sort of palpitation. When the Aurora is extensive, these beams, although constantly shifting, converge towards the zenith,

where a centre, or superb auroral crown is formed. As the phenomenon diminishes in intensity, the jets continue, but the crown shifts, and is seen sometimes on one side of the sky, sometimes on the other: at length these movements cease; the light withdraws itself nearer and nearer to the western horizon; the obscure segment, as it too diminishes, becomes luminous; at length, every trace of it disappears. The most complete account given of the northern Aurora, as seen in its own latitudes, is that by the French scientific Commission, which, in 1838-39, spent a full winter at Bossekop, in West Finmark, N. lat. 70°. We shall describe the main features of the phenomenon, on the authority of M. Lottin, one of the members of the commission—referring for details to the great work published at Paris, at the expense of Government. In the evening, between four and eight o'clock, the light mist which prevails almost constantly to the north of Bossekop, to the height of about 4° or 6°, becomes coloured over all its upper rim, or rather appears fringed by the light of the Aurora existing behind it. This bright border soon grows more regular, and merges into an indistinct arc of pale yellow, whose extremities rest upon the earth: an arc which rises gradually up into the sky, its keystone always nearly coinciding with the magnetic meridian. Soon afterwards dark streaks separate the luminous matter of this arc; the well-known rays are then formed; these stretch out, and draw themselves in, now slowly, now almost instantaneously; they dart, shiver, and dance,—augmenting and diminishing suddenly in splendour. The feet, or roots of the rays are always especially bright, and continue during all the display to form a shining arc more or less regular. Their length is very various; but all converge towards that point in the heavens indicated by the prolongation of the south pole of the free magnetic needle. At times they are quite prolonged, *en masse*, to this point of union; forming there the fragment of an immense luminous cupola. The arch in the meanwhile is itself mounting towards the zenith, and is generally shivering, as if with undulations; these undulations or waves of light, passing for the most part from west to east. Sometimes, although rarely, retrograde undulations may succeed; the waves, after passing from one side of the heaven to the other, retracing their steps, and flowing back to their point of departure. This alternation of waves in the luminous arc, is sometimes surpassingly grand. At one time, the alternating movement has the appearance as if a brilliant curtain were above us, its folds agitated by the winds; and, again, the edges of the arc having separated from the actual horizon, their folds become very complex, inwrapping each other, and presenting to the astonished spectator a variety of the most graceful curves. The remarkable appearances now described, are presented in our engraving. The

AUR

brilliancy of the rays or shooting sheets, is, during these extraordinary changes, subject to sudden augmentations of intensity; so that it comes to surpass that of stars of the first magnitude: they dart out with extreme rapidity, and the curves spoken of, form and reform, as quickly as the twistings of a serpent. Then the rays become coloured; the base red, the middle green; while the rest of them presents a clear yellow. These colours preserve, without exception, their respective positions, and are always of admirable clearness; the red is like blood; the green of a pale emerald. Soon, however, the phenomenon shows signs of having exhausted its vigour. The splendour diminishes, and the colours disappear; the arch, meanwhile reforming, continuing its ascensional progress and approaching the zenith, and the rays which dart from it becoming, therefore through mere effect of perspective, shorter and shorter. At length the summit of the arch reaches the *magnetic zenith*—(the point indicated by the prolongation of the *free magnet*). The base of the rays is thenceforward alone seen; if they continue coloured, they seem like a large red band, through which the green of their upper parts can be distinguished, and if the undulating motion formerly spoken of, has not ceased, their feet continue to form a long sinuous and undulating zone. In the interval occupied by these changes, other or secondary arcs appear; and while they preserve their distance, they exhibit a succession or regular series of aspects, such as has been described. Sometimes, however, they approach and mingle with each other; so that it is easy to conceive that the appearances produced are literally indescribable. The celestial vault becomes an immense and magnificent dazzling cupola, overhanging a world covered with snow, which again is environed and set within an ocean black as pitch.—So much for the general phenomena presented by the Northern Aurora. In an elaborate memoir published by the French Commission, M. Bravais has subjected all important details to a close scrutiny: he has spoken minutely of the *Obscure Segment*; of the *Arch*, the *Rays*, and the *Crown*; of *Auroral Sheets*; the motion of *Palpitation*; of the *intensity* and *colour* of the *Auroral Light*; and of its *distance*. The latter is represented as between 60 and 120 vertical miles—miles upwards from the earth's surface: the determination is very uncertain; as, indeed, is sufficiently shown by its indeterminateness. No doubt, however, the auroral light is *thick*; i.e., there is a large interval of space between its inner and outer surface. The chief value of M. Bravais's determination, will be found in what we have now to say regarding conjectures as to the nature and cause of the phenomenon. These are designated expressly as *conjectures*.—It is needless to dwell on the earlier theories. That such men as Halley, Mairan, and Dalton, chose to put forth explanations concerning a phenomenon they had really never seen, or whose phases—not the most ordinary—

AXE

had received any determinate or numerical *firing*, only shows that the exercise of the generalizing faculties is comparatively pleasant, and that the force of them, in most good minds, quite overpowers the checks which ever and anon are applied by persons having more of the *observing* instinct.—M. Biot is an authority of a different order; he knew something, although not everything, of the totality of the phenomenon;—we do not think, however, that he made much of it. Holding by the theory of its *electric origin*—a doctrine suggested by its evident connection with terrestrial magnetism—he considers its elements probably composed of metallic particles of an extreme tenuity, that serve as conductors between the various atmospheric beds, which are known to be very unequally charged with electricity. Suppose then, two similar columns suspended vertically in the atmosphere, the electricity of the beds of air lying from the top to the bottom of these columns, will find these conductors more or less perfect; and if the tendency of the electricity to get into equilibrium surpasses the resistance opposed by the imperfect conductive powers of the said columns, a long vertical discharge will follow, sparkling from one metallic molecule to another; variously to the spectator, because he looks through a *thickness* of beds, and so producing a shifting auroral phenomenon. Is it possible to imagine a grave philosopher more grossly mistaking his function than M. Biot has here done? We acknowledge his great services; but, in this instance, he is only playing at toys. A more rational speculation by far, is that of M. Kaemtz. He attributes auroral phenomena to an electrical *induction* manifested in the atmosphere, and produced by changes in the magnetic intensity of the globe. Neither will this notion, albeit rather a favourite one, account even for the known facts.—It is utterly vain to search at present for a theory of the Aurora. What is known is this,—the direction of the auroral *jets* or *rays* and the position of the *crown*, have a connection with the magnetic meridian; and the aurora produces great magnetic perturbation.—Further lights as to this singular subject may be found by the student under our various notices of ELECTRICITY and MAGNETISM. As to theory or explanation, we must even *observe* and *wait*.

Autumn. The third season of the year; so called from the *increase* of the fruits and plants coming to full maturity. It commences on the 23d of September, or sometimes the 22d, the day of the autumnal equinox, just when the sun is about to enter the constellation Libra. It closes on the 21st or 22d of December, when the sun enters Capricorn. It lasts, in all, 89 days, 16 $\frac{1}{2}$ hours. During its continuance, as the sun is continually descending in the signs, the days grow shorter and shorter, and the nights lengthen.

Axe or Axis. It is difficult now to define this technical term, its use has become so ex-

ture, and its meanings so varied. Perhaps the following will be found to comprehend most of its legitimate significations:—If any line holds a symmetrical position with respect to any system, motion, or phenomenon, or if it be such in its relations to that system, motion, or phenomenon, that it is convenient to distinguish it by a specific name; that line is termed an *axe* or *axis* of the said system, motion, or other phenomenon. Very many applications of the term *axis*, justifiable by no closer definition, will be found throughout this Dictionary.

Axis, the Principal. A term indicating a very important phenomenon and general theorem in that part of rational mechanics which relates to the rotation of solid bodies, or rigid systems of points. Briefly, the subject may be explained as follows:—If any solid body, of whatever figure, is struck in any place not exactly opposite its centre of gravity, it will begin to rotate, as well as to move onwards. It rotates at first around an axis, named the axis of spontaneous rotation, and the position of which depends on the kind of blow given. But this axis is not generally the fixed one. Unless that happens to be a *principal axis*, it shifts; and very soon the body comes to rotate around an axis which it retains, or which does not shift: this is called a *principal axis*. Now, every rigid system has at least three such axes, or right angles to each other, and these are called the *three principal axes*. Some bodies or rigid systems have many such—in a sphere, for instance, every diameter is a principal axis; but, as already said, every rigid system has at least three. The position of these axes can be determined in every case by analytical processes, without much either of skill or trouble. The *principal axes* at one time played a considerable part in mechanical theory, and they are still of considerable importance. They enjoy one property, which, as it is often referred to, may not unfitly be explained in this place. There is a technical phrase connected with rotatory motion, by name *moment of inertia*. The meaning of it will be understood from what follows. Suppose a solid body, or a rigid system, in the act of rotating about an axis, with a definite angular velocity; and while it so rotates, let us fancy a particle, m , at rest suddenly attached to it, at a distance of r from the axis. It is evident that the angular velocity will now be diminished, because the body has got the new particle m to drag along with it. Now, it is diminished to the following extent:—The angular velocity in the first instance is expressed by a formula in a fractional form, and to find the new angular velocity we require to add the quantity $m \times r^2$ to the denominator of that fraction. The quantity $m \cdot r^2$ is called therefore the *moment*, or the effective amount of the *inertia* of the added particle—the measure of the force with which it has dragged back the system to which it had become attached. Such being the measure of the moment of inertia

of a single particle, it is easy enough, by analytical methods, to determine the moment of inertia of any number of particles, or of any body or rigid system, with respect to any axis around which rotation takes place. Now, the *principal axes* enjoy this property,—with regard to one of them, the moment of inertia of the rotatory mass is greater than with regard to any other axis passing through the point at which they intersect; and with regard to another of them, the same moment of inertia is less than with regard to any other axis. In other words, we have the condition at once of a *maximum* and a *minimum* value of the *moments of inertia*. The geometer who first very clearly investigated this curious subject was Euler.

Axiom. *Logic, deductive or inductive*, has no power save this,—it can elicit new matter out of premises, or combine and generalize separate facts or determinations. A *deductive science*, then, must accept or presuppose all those premises, out of which, whether by analyzing their contents, or by combining them variously, its whole possible fabric must be reared; and an *inductive science* must equally accept, as its foundation, certain general truths or laws, and certain general principles or laws of combination, on the ground of which, and by means of which, its further discoveries are to be interpreted and co-ordinated. Those fundamental *elements* or *acceptances* are AXIOMS. The more general the science is, the more general are its axioms; but every *special science*, logically considered, must have its *special axioms*. The sources of axioms, or the roots from which they spread, are threefold. 1st. There are laws of the mind, in obedience to which alone the logical faculty can contemplate either the external world or the mind itself. The laws which have regard to the latter are often in metaphysical language termed *intuitions*; but the word is faulty, for the laws in question are very various. The laws under which we contemplate the external universe, on the other hand, are, although various, not very complex; they are included under what Kant has termed the *laws of our sensibility*, and the *categories of the understanding*. 2d. Propositions that result from universal experience in the elementary physical sciences, such as the sciences of *motion* and *force*, must be accepted by them as axioms. But the certainty of this latter class of axioms is less than that of the former. The laws of the observing faculties are necessarily universal; but the results, or so-called results, of universal observation, must, at the best, rest on but secondary evidence. 3d. Arranging the sciences according to a hierarchy, or in order of their complexity, the elements or axioms of the higher class must always rest upon the demonstrations of the lower. This third class of axioms, accordingly, has only a third or still inferior degree of certainty. For practical illustrations of the doctrines here expressed, compare

AZI

GEOMETRY; MOTION, LAWS OF; PARALLEL LINES.

Azimuth. The azimuth of a body is an arc measured on the horizon, intercepted between the meridian or circle through the zenith of the place and the poles, and a circle through the zenith, the nadir, and the given body. The altitude of the

BAL

body is measured along this circle, upwards, from the nearest point where it meets the horizon. It is evident, that when we have given the altitude and azimuth of a star at any given moment, we shall be able to point out its exact position in the sky.

Azimuth Compass. See COMPASS.

B

Balance. The balance is employed as a measure of the quantities of matter contained in substances. If all bodies were constituted similarly—if their density were the same, and their constituent atoms alike in nature as well as shape—we should have a sufficient measure of the quantity of matter which a body contains in the volume which it fills. Bodies are not, however, thus similarly constituted, and, when we wish to compare their masses, we require to look for another standard. We find this in the principle that equal forces, or the same force, will produce effects upon bodies proportional to their mass. Thus, if two equal bodies (equal in mass) be solicited by equal forces, their motions will be, in every respect, similar. If two equal bodies, under the action of certain forces, have acquired, at the end of any given time, the one a velocity sufficient to carry it through 10 feet in the next second, and the other a velocity capable of carrying it through 20 feet in the same time, the last force is double of the first. If, again, the body in the first place have been three times in mass that in the second case, the latter force will be only $\frac{2}{3}$ of the former. In the case of the balance we have equal forces acting upon equal masses. The two motions which would result are, as it were, however, set over one against the other, and there is obtained, therefore, no motion. The two bodies to be compared are set, the one at the one end, the other at the other end of a bar, which rests at its point of bisection upon supports. The principle of the lever teaches us, that, if the bar be truly bisected, it will turn, upon its supports, in a vertical plane to the side of the greater weight. We see the same principle illustrated every day, by children riding on logs of wood, for example, where, if the arms of the log, from the point of support upon which it turns to the place where each boy sits, be equal, it immediately inclines towards the heaviest. The least inclination, therefore, of the bar from the true horizontal, indicates to us the inequality, either of our masses, or of our lever arms. If we are confident of the perfect equality of the latter, we may be certain that the former are unequal.

This is the general principle of the common balance. As, however, perhaps no instrument is more important in physical investigations, we will make a few remarks upon the methods which have been employed to secure a perfect balance.

There is one method employed to secure a true result, from even an imperfect balance, which is very ingenious and very useful. We refer to the method of *double weighing*. It is almost impossible to make the arms of a balance exactly the same in length and thickness. There is always some little difference, which, in extreme cases, might come to cause errors perfectly sensible were it not for this method. Even the influence of temperature upon a body like the bar of iron usually employed for the *beam*, necessarily not quite homogeneous throughout, causes considerable deviations. The method of double weighing is as follows:—We first bring the given body to exact equilibrium, by weights placed in the opposite scale. Then take it out of the scale; and restore the equilibrium thus disturbed by placing shot, or some weights, the exact amount of which you know, in the scale, instead of the original body. The weight of this quantity of shot will be the true weight of the body. It is easy to see how this method of measurement gets rid of all such causes of disturbance as inequality of the arms. We have simply two bodies successively placed in the same circumstances, and producing successively the same effect upon a third body, which has remained throughout the process in the same circumstances. As this effect depends (being the action of the *force* of gravity upon the bodies) upon the mass of the bodies, we must conclude their masses to be exactly equal.

The two conditions which it is most important that a balance should fulfil are *sensibility* and *stability*. The former requires that a very small difference of weight shall cause a deviation from the horizontal line. Thus, Ramsden made a balance for the Royal Society, so sensible, that one-millionth part of a pound was capable of turning it. Balances are now quite commonly constructed capable of detecting differences in weight of a thousandth of a grain, or one seven-millionth of a pound. The latter requires that the balance, when disturbed, shall rapidly return to rest. We may see at once that there is something of opposite in these two conditions; the latter being such that, when it obtains, it may destroy a deviation from the horizontal before it has become noticeable—that is, such that, even with a small inequality of weight, the balance may apparently be in perfect equilibrium. In fact, they may be shown theoretically, not indeed to be quite in-

compatible, but to be so to a considerable extent. In the mercantile balance, stability, therefore, being there important for the economy of time, is the quality chiefly desiderated. In the philosophical balance, again, where economy of time is of much less importance than perfect accuracy, sensibility is principally sought. The condition of stability is the following:—That the centre of gravity of the beam and scales should be *below* the point of suspension. The stability is greater the farther the centre of gravity is below the point of suspension. In that case it will be clear that any disturbance of the balance, while it does move its centre of gravity, will move it through a less angular space, when we take the point of suspension as the centre of angles, and that, in consequence, the vibrations will more speedily cease. It is more important, however, for us to know the conditions of the *sensibility* of the balance. One evident condition will be, that there be as little friction about the points of support as possible. Could it be that there should be no friction, the very smallest difference of weight would move the balance from its place; for nothing, in that case, would oppose the tendency of the preponderating weight, until the deviation of the centre of gravity of the instrument from the vertical position, under the point of suspension, became great enough that its tendency to its original position under this point should come into play. In consequence, the beam rests upon what is called a knife-edge, supported upon highly polished agate planes. Similarly, the little ring, by which we suspend the weights and scales, should have an inner surface of agate plate, or, at all events, of highly polished steel; and the lower edge of the hole through which the ring passes should be a knife-edge. In order to insure the highly polished steel of these knife-edges from losing its sharpness too speedily, the beam is lifted up by a sort of fork, from the ordinary point of support, when the balance is not in use; this being screwed up, by a screw at the bottom of the balance, so as to catch its arms on either side. To prevent, further, the accumulation of dust, or the gathering of moisture, upon the balance, and the consequent rusting and increase of weight of parts of it, it is usually kept in a glass case, within which a salt, such as chloride of calcium, which absorbs moisture strongly, is contained. It is important further to notice that, as steel and iron are very apt to acquire magnetic properties, especially if kept where magnets are kept, as in philosophical instrument rooms, frequently, the balance should be constructed, as much as possible, of brass.

There are some points to be attended to in the plan of construction of our balances, besides these more mechanical details, which it is important to notice. Thus,

1. All other things remaining equal, the sensibility of a balance will be increased as the length of its arms increases. The reason for this

will readily be seen. The preponderating force, when there is one, acts with a longer leverage. (See LEVER). It is farther from the point of support, and although, therefore, itself less, it may produce an equal effect with a greater force acting with shorter leverage.

2. If we add to the weight of the beam we diminish the sensibility of the balance. The reason for this, also, will be readily apparent. The weight of the beam presses downwards upon the point of support. Now, the heavier this pressure is, the greater will the friction on that point be (see FRICTION), and that in the exact proportion of the pressure. According to this same principle, it is worthy of notice that the sensibility will increase according as the loads in the scales diminish. The two loads act together at the middle of the beam, and produce also a pressure of the knife-edge upon the agate plane. The greater this pressure is, the greater will be the force of friction which must be overcome before a slight difference in weight will produce a deviation from the horizontal position of the beam. In ordinary philosophical balances, however, we have not often need to consider this latter application of the principle. The weights tested are usually very slight, and bear, in consequence, a very small proportion to the weight of the beam and scales, so that the frictional force is increased by them in an indefinitely small ratio. If, however, we measure considerable weights, it is necessary to keep this in mind when we decide on the sensibility of the balance.

3. A third law is, that the sensibility is increased by diminishing the distance of the centre of gravity of the beam from the point of suspension. We saw already how this diminished the stability of the balance, and it will be clear that, so far as this goes, the stability of the balance will be exactly in the inverse proportion of its sensibility. The same principle will require the centre of suspension to be very near the point which bisects the line joining the points at which the scales are suspended. It is at this point that the weight of the scales and the load acts, when the beam is truly bisected by the point of suspension, and this point ought to be near the centre of suspension, for the same reasons as the centre of gravity of the beam. The coincidence of either of these points with the point of suspension would tend to produce unstable equilibrium.

A needle is usually attached to the centre of the beam, so as to be exactly perpendicular to the line of the points of suspension; when this hangs in a vertical direction, the balance is in its true position of equilibrium. There is frequently a graduated scale attached, by which we may read off the angle of deflection. We are thus enabled, also, to tell when equilibrium will be restored, before it has taken place, by the equality of two successive deviations of the needle from the vertical.

In order, further, to give us a power over the

BAL

sensibility or stability of the balance, according as we require it for different purposes, a small *nut* is attached to a screw at the top of the beam, which we can screw down—so lowering the centre of gravity of the beam—or screw up—so raising it—so as to have the distance of the point of suspension from the centre of gravity of the beam, under certain limits, what we desire it to be. It is evident that the possession of such a power is a desideratum, when a balance may be required either for very delicate philosophical investigations, or for more ordinary purposes.

We subjoin a figure of the ordinary balance.

Bent Lever Balance depends upon nearly the same lever principle as the common steel yard. It is an elegant instrument, but this we believe to be the best that can be said of it. It consists of a bent lever, fastened at the centre on a pivot, having at one end a scale suspended, while at the other the lever ends in an index needle, just before which is a heavy weight. This weight keeps the lever nearly vertical when there is no weight in the scale. There is a graduated scale annexed to the balance, along which the needle runs when the lever moves. When a weight is put into the scale, the tendency is to raise the lever nearer to a horizontal position—and the needle indicates the extent of this. We can easily comprehend then, how the instrument can be graduated just as the common steel yard is. It has not its defect, that the standard weight employed may be lost, and not easily recovered. The weight here is part of the lever arm itself.

Hydrostatic Balance.—This instrument depends upon the hydrostatical principle, that bodies immersed in a fluid are subject to a force, resisting gravity, and equal in amount to the gravitation of quantities of the fluid contained under volumes equal to those of the bodies. In consequence, they lose just so much of their weight when they are weighed while in the fluid, as the weight of an equal volume of the fluid itself amounts to (HYDROSTATICS). Taking advantage of this principle, the hydrostatic balance is chiefly employed for the measurement of specific weights, or specific gravities of solids

BAL

and liquids, and of densities where the body weighed is homogeneous. It consists, in its simplest form, of an ordinary balance, to the bottom of one of the pans of which a hook is permanently attached—so as not however to disturb the equilibrium—the pan itself being lighter than the other by the weight of the hook. A given body is then—if it be a solid—weighed as usual, and its exact weight recorded. A fine silk thread is then attached to the hook at the bottom of the pan, and if great accuracy be required, the weight of this, if at all sensible, will be also noted down, and used to correct the result. The body is then attached to the thread, and dropped into the fluid. If the weights which formerly produced equilibrium have been retained in the scale, they will now draw the body until its lower edge just touches the water—where the force of cohesion of the body to the water may or may not hold it, as the case may be. If, however, this effect is to be prevented, we must take weights from this other scale, so as to keep the body wholly in the water. Note the amount of weights necessary for this. Then as we have had first the weight of the body—then the same weight diminished by that of an equal bulk of water, the difference between the former amount in the scales, and the new amount will give the weight of an equal bulk of water—that is, it is equal to the weight of those shot or ounces, or whatever it may have been, which we took from the other scale. We obtain thus the weights of equal bulks of water and of the given body, and dividing the latter by the former we have the specific gravity required.

Theoretically we would require to take into account in balancing, that our weights, and the things weighed may displace different quantities of air, and so, in this case we would require to remember that the weight that we obtain in the two cases is that of a body weighed successively in air and in water. We must remember, however, also that our weights themselves are weighed in air, and even were the whole weight of a volume of air equal to that of the bodies we operate with, to be neglected, very little error would result. The bodies we operate with in obtaining specific gravities are very small; and it takes about 21,400 cubic inches of air at ordinary temperatures to weigh a pound.

When we wish to find the specific gravities of fluids, one method will be to weigh equal weights of the same substance in air and in water, and the given fluid, successively taking the one to weigh in water, and the other in the fluid.

In that case we should have the weights of equal bulks of water and of the fluid to compare, and we shall obtain the same result as before.

In using this balance it is necessary to see that the solids used be not soluble in the very least degree in any of the liquids used. If they be soluble in water, for instance, we must employ other liquids in which they are insoluble,

and whose weight, as compared with that of water, is sufficiently known. No solid should be employed which has loose particles adhering to it, for the least motion in any liquid will rub them off, and thus make the bodies actually weighed in the air and the fluid in reality two different bodies. We annex an engraving of the instrument.

Spring Balance.—This instrument is sometimes more convenient than the ordinary balance. It can be put in one piece, and is, therefore, more portable. It consists of a metal spring, which is elongated by weights suspended at one end of it, or shortened by weights pressing on the other. The measure of lengthening or shortening is taken as determining the weights in question. In order to graduate the scale for the determination of weights, one ounce, two ounces, three ounces, &c., are respectively employed, and the elongation or shortening of the spring carefully marked. Weights which produce the same amount of elongation or shortening are considered to be acted on by the same gravitating force. A common instance of the spring balance is found in the letter-weigher. The instrument is also frequently employed by grocers. It is subject, however, to one great disadvantage. It loses its power in heat, and its elasticity increases in cold. Now if, on each occasion of employing it, we used both the standard weights and the body to be weighed at the time, and inferred the weight of the body from the effect produced by it, being equal to that produced by a given standard weight, this effect would correct itself as it does in the ordinary balance; for, though we could not tell absolute weights, we could compare as usual. This method, however, has been abandoned, and we graduate a scale according to the elongations or shortenings produced by standard weights, at one time and at standard temperatures. In fact, we measure the effect produced on the spring by certain weights, once for all, and therefore at a fixed temperature, and with definite elastic forces in the spring. In heat, therefore, a body, having less elastic force in the spring to overcome, will push it further down on the scale than it would at standard temperatures, and will so appear heavier than it ought. The reverse effect will occur in excess of cold.

There is yet this other defect to which spring balances are liable—that, after much use, the spring comes to lose its power, and the same effect is produced as in the case of unusual heat. Practically, also, it is usual for the spring to be concealed, in order to keep it from injury or dust. In consequence, it is not uncommon that the balance should be put all wrong for days, by some dust gathered inside, and the error not be detected.

These defects preclude us from considering the spring balance generally, as much more than a convenient instrument. One advantage, however, which it has over the common balance, gives it an importance in a philosophical point of view. With the common balance, it is not a matter of any importance whether the actual force of gravity vary or continue constant at the places where it is used. For the extent of the balance itself, at any

given time, gravity is always the same; but it is not the same, for example, at the equator and at Glasgow. The common balance compares the mass of a given body with that of a lb., for example, and decides it to be the same, because gravity, at the place, produces the same effect upon it. Remove the balance from Glasgow to the equator, and we have the same result. The common balance, therefore, assuming the forces acting at the two extremities of the beam to be equal, compares the masses rather than the forces. The spring balance measures the forces directly. A body, such as a lb., will not produce the same elongation of a spring at Glasgow and at the equator, under the same temperature. In the case of the common balance, we have the different forces of gravity acting; but in both cases they eliminate themselves, as it were. At Glasgow, the gravitation pulling at the one end of the beam neutralizes the same Glasgow gravitation at the other end; so, also, at the equator, gravitation in each case is considered twice. In the spring balance, on the other hand, it is considered only once, and a greater gravitating force, just like any other greater force, produces a greater movement of the spring. Hence the spring balance is useful in determining for us the value of the gravitating force at various localities. This gravitating force varies, since the earth is not spherical, and the mass of the earth concentrated at its centre of gravity is not equidistant from bodies at the surface. The spring balance becomes thus a measure of this ellipticity. The ordinary pendulum, however, also depending for its movements on the amount of gravitating force, measures it better. See FIGURE OF EARTH and PENDULUM.

Steel Yard.—The steel yard, or *Roman balance*, is another instrument also used frequently for convenience. It consists of an ordinary beam of iron supported on a pivot dividing it unequally. At the shorter end is a scale, in which the body

BAL

to be weighed is placed. Put there first a lb. weight, and take the same weight, for instance, and shift it along the longer arm until equilibrium results. Then put two pounds weight in the scales, and shift the weight out along the arm until equilibrium result again, and so on. Mark the points where your weight equilibrates the various standards put successively in the scales. Whenever we have to weigh a body then, we shall just shift this lb. weight along the line of the longer beam until equilibrium is produced, and then read off the scale, at the point where it is suspended.

The principle of the steel yard is just that of the common lever (see *LEVER*), that the weights, in order to produce equilibrium, must be exactly in the inverse ratio of the arms. It is not at all necessary that the weight which we employ should be any standard weight, such as 1 oz. or 1 lb., but it is necessary that we should always use the same weight for weighing with, which was employed when the bar was graduated off. If we lose it, our instrument can be of no more use to us, until by trial we recover it. For convenience of recovery it is better that it should be some standard, easily replaced if lost, and the selecting of that standard is just made according as the weights to be usually measured are heavier or lighter.

The steel yard is an instrument not susceptible of very great accuracy. Its only advantage is, that it enables us to employ any one weight in all our measurements. It is not employed in philosophical experiments to any extent. We annex an engraving of the common steel yard.

Torsion Balance.—An instrument by means of which we may measure very small attractive or repulsive forces. It was first employed by the inventor, Coulomb, in his electrical experiments. A very fine thread is suspended from a fixed point. A weight is added at the end of it to steady it, and prevent vertical motion as much as possible. A needle is then fastened to the thread between the top and the weight, of such length as just to follow, when it revolves, a graduated scale of degrees annexed to the instrument. When we wish then to measure the smallest forces, we make them act at the extremity of this needle, which is deflected by them from its original position, proportionally to the forces. In fact the only force which prevents the needle from moving quite freely, all round the circle, is the recoil of the thread from the thrust which this would give it. This is called the force of *torsion* (see *TORSION*), and as we can calculate its amount in the

BAL

case of each particular thread, for a certain deflection, we can tell the amount of the attractive or repulsive forces. The needle comes to rest just when these forces and that of torsion are equal. We annex an engraving of Coulomb's torsion balance.

Balancing Wheel. See *WATER WHEELS*.

Ballista. The name of an ancient warlike engine, adapted to throw stones, sometimes as heavy as three hundred-weight, against the walls of a besieged city. It was nearly square-shaped. It was capable sometimes of throwing stones a distance of a quarter of a mile. The *scorpio* and *onager* were similar instruments, of which we know, however, nothing else. See also *CATA-PULTA*.

Ballistic Pendulum. An instrument employed for the purpose of measuring the velocity of musket and cannon balls. It consists of a very strong wooden pendulum, having a thick ball of wood, plated with iron, at the bottom, against which the bullet to be experimented upon is fired. The ball ascends, pulling out a ribbon which is attached to it, so as to be capable of being drawn out with little or no force. The length of this ribbon tells us to what height the ball has risen. In fact, it will be the length of the chord of the arc which the pendulum describes in its first oscillation. If, then, we know the weight of the bullet, and the weight, form, &c., of the pendulum itself, with the position of its centre of gravity at which its weight acts, we shall be able to measure the velocity of the bullet by the quantity of motion which it is capable of communicating in this way. The process by which we arrive at the numerical result is somewhat intricate, but the reader will easily understand the principle upon which it proceeds. Whatever quantity of movement the bullet has lost, the pendulum has gained; and, if the bullet loses all its motion, the whole amount of it may be measured by the actual motion of the pendulum.

Balloon. The balloon depends upon the principle of Archimedes for its power. That principle applies to every case of bodies immersed in a fluid. According to it, every body, in such circumstances, loses just so much of its own weight as the bulk of the fluid which it displaces comes to. Suppose, for example, a stone of 1 lb. weight placed in water. Imagine, for a moment, the outline of the stone remaining as an infinitely thin shell, through which the water enters, and which it fills. Suppose this shell taken out and

weighed while filled with water, and suppose it weighed also while filled with the stone. According to the principle of Archimedes, the weight of the stone when in the water, together with the weight of the outline, as it were, of the stone filled with water, will just make up the original weight of the stone out of the water. Now, the balloon is a body immersed, like the stone, in a fluid—the air—and the same law applies to it. It loses so much of its weight as an outline of its form, so to speak, filled with common air would weigh. There is this difference, however, between the two cases:—the stone has still weight left by which it descends; the balloon, on the contrary, ascends. We shall see the point of union between the two cases more readily, if we imagine gravity—the force of the weight—as represented by a man pulling right downwards a string attached to the stone and the balloon, respectively. Suppose that another man represents the loss of weight which each experiences—the contrary weight of the equal masses of fluid, by pushing the bodies upward. In the case of the stone, the man pulling downwards is the stronger of the two, and the body descends. In the case of the balloon, the man pushing upward uses most force, and the body rises. The principle is precisely the same in both cases.

The methods of securing this preponderance of ascensive force are readily suggested. We know what it is in every case—a force, pushing upward, equal to that which draws downward a body of common air which could be contained within the outline of the balloon. We require, then, to see that the downward force be less than this. The materials of the balloon—the silk, the cords, the car—weigh more than the air they respectively displace; and, when the balloon is used for aerial voyages, the travellers weigh considerably more also. There is, then, so far a preponderance of the downward force. There is left us, however, the internal space of the balloon. Now we cannot leave this unoccupied—in which case we should have the upward force gained without any counterpoise of downward force—because, without very strong materials, the sides would be crushed in. The atmosphere, we know, presses with a force of $14\frac{1}{2}$ lbs. on every square inch. A silk bag, utterly empty, would collapse into two silk plates under this pressure, and we should thus lose our advantage as soon as we had got it. If we used stronger materials, so as to avoid this, such as iron and copper, the first preponderance which we have noted—that of the downward weight of the materials over the upward part of an equal quantity of air—would be very great indeed, if they were made thick enough to resist the entrance of air at every point, and we should have but little, if any advantage from our balloon. We have to fill it then with something which shall keep our bag distended, and so retain the space which we are anxious thus to turn to account, and which yet shall be lighter than common air. Heated air was employed for

the Montgolfier balloons, hydrogen gas for the ordinary balloons made now. We have, then, the preponderance of the downward force, as far as regards materials; and of the upward, as far as regards the filled space. If the difference of specific weights of the light body and air be considerable, or of the materials and air inconsiderable, and if the proportion of space which they fill be small compared with that which the bag of the balloon, if we may so call it, fills, we shall have a very powerful upward force as the result of the whole.

One practical caution we should wish to repeat, because it depends upon a very important physical principle. The aeronaut who fills his balloon with hydrogen gas must not put in it as much as it can hold of the gas. If he do not—if he put in, for instance, only half what his balloon will contain—he will certainly commence the ascent with less than half the force with which he might have done so. His balloon will be squeezed down to half the size; and, according to Mariotte's law, when it reaches that, the pressures inside and out, being equal, will balance. He will only thus have half the apparently available difference of weight of hydrogen and common air. When he has ascended, however, not so quickly as he might have done, a considerable way into the atmosphere, his circumstances will have changed. The atmosphere is no longer so dense. All the weight of air beneath him, which lay on the strata of the air at the surface, does not press on the air in which he now is. It does not press then so heavily on the sides of the balloon. Now the hydrogen inside is only kept in the space of half the balloon because there is a pressure outside which balances the pressure in that case. When the pressure outside becomes $\frac{1}{2}$ of what it was at first, it will occupy no longer half the space, but $\frac{1}{2} \div \frac{1}{2} = 1$ of the space (see MARRIOTTE'S LAW), that is, $\frac{2}{1}$ of it. When, again, the pressure becomes only half what it was, the hydrogen will occupy twice its original bulk, and fill the whole balloon. Now here lies the advantage which he has reaped from not filling his balloon. The pressure outside is now $7\frac{1}{4}$ lbs., according to our supposition, that within, according to Mariotte's law, is the same, because, as the space of the original hydrogen increases (which is now double of what it was, the pressure which just balanced, and was therefore just equal to the atmospheric pressure) decreases in the same proportion. There is, then, no strain at all upon the canvas at the height where the atmospheric pressure is diminished by one-half, that is, about the greatest height to which Gay Lussac went. If, however, the balloon had been filled, and if it had reached this height, there would have been a pressure inwards of $7\frac{1}{4}$ lbs., and a pressure outwards (the original pressure) of $14\frac{1}{2}$ lbs. per square inch. In all likelihood, then, the silk or canvas would burst, and the unhappy balloonist's voyage terminate. See AERONAUTICS.

BAR

Barbette. A term of fortification, denoting a sort of battery. It is a small hillock of earth, flanked by works on which cannon may be placed, which are fired over the wall, instead of through embrasures.

Barbican. A term of fortification. It marks any small outwork, like a wall—pierced with shot-holes, intended to mask a bridge or a gate, or a covered way, or any object dangerously exposed.

Barometer: etymologically, a *measurer of weight*: a name given to one of the most important instruments of meteorology,—its object being to measure the *weight* of the *superincumbent column of air*, and so to enable the inquirer to note its variations. In common estimation, this instrument is a *weather-glass*, prognosticating the occurrence of rain, &c. &c.—it does not, however, give any direct indication except the one now specified: the probabilities of rain, &c. are inferences only, and dependent for their degree of accuracy on the mode by which very imperfect meteorological theories have been able to connect the other phenomena of the atmosphere with its *weight*. The principle of the barometer is very

simple. Suppose a tube, AB , closed at the top, and of considerable length, to be filled with mercury, or any other fluid, and then turned into the position occupied by it in the diagram, it is easy to see what must occur, if the end D is left open. It is this: the mercury will descend in the tube, and reach a level, c , determined in this wise,—the height of the column CD must be an exact counterpoise to the weight of the whole column of air resting on the open surface of the mercury at D , and so pressing the mercury or other fluid up the tube. The weight of the *column* of air may thus easily be found, if the exact specific weight of the liquid in the tube has been previously ascertained. Any liquid whose specific gravity is known will suit the purpose: water, for instance, is employed in the water barometer. On two accounts, however, mercury or quicksilver is the liquid employed in practice, viz:—*first*, its great specific gravity enables a comparatively short column, never more than thirty-one inches, to counterbalance the whole column of the atmosphere, thus confining the size of the instrument; and *secondly*—because of the high temperature of its boiling point, the elastic force of its vapour at ordinary temperatures is extremely small; so that for ordinary purposes the disturbing or reactive force of the mercurial vapour filling the space AC of the tube may be neglected. Without entering on minute details, it will be evident that the chief mechanical requisites of the barometer are implemented in such an instrument as the following:—Within a brass tube, capable of being suspended by a ring at A , or fitted by other means to be

BAR

placed *vertically* with the greatest exactness, let there be a glass tube, closed at the top, and filled with mercury. The other open end of the glass tube is plunged into mercury contained in a box $CC'DD'$; the surface of the mercury being seen at c' . Attached to the brass tube is an *ivory* or *platinum* point, seen near c' ; and by a screw, A' , connected with the *moveable* bottom of the box, $CC'DD'$, the surface c' of the mercury in the box can always be brought just to touch the end of the ivory or platinum point. This platinum or ivory point is the *zero* or commencement of the scale by which the height of the mercury in the tube is measured. The upper part of the scale, as much as includes the whole possible range of the mercury, as caused by variations of atmospheric pressure, say from 25 to 32 inches—is engraved on the brass tube, to which, for minuter readings, a sliding vernier, $BB'B''$, is attached. An observation may be conducted in this wise. The lower surface, c' , being first brought to the ivory point, the position of the upper surface is examined, as it appears through the slit EE' in the tube. The sliding ring $BB'B''$ is then brought by an attached screw, until its plane be a tangent to the summit of the meniscus which terminates the mercurial column; a careful reading of the scale and vernier will then give the height of the column. The operation seems easy,

Fig. 2.

but it must be performed with solicitude; especially as from the great specific gravity of mercury, the slightest error will cause a great error in the weight of the column deduced from it. But this process, however great the accuracy with which it may be gone through, does not suffice to enable the inquirer to state the real weight of the Air. There are *corrections* to be applied in compensation of *errors*, occasioned partly by inaccurate construction of the instrument, and partly by physical causes. The Errors in question may be classed under two heads,—those which are absolute and invariable—characteristic of the instrument under *every* condition; and those which vary according to the circumstances under which each observation is made. We shall discuss them separately:—*I. Absolute or Constant Errors.* One set of these absolute errors, inhering in all ordinary Barometers, and rendering them useless for delicate observation, ought to be prevented by the maker of the instrument, and the mechanician setting it up. These arise from the impurity of the mercury employed, and from the inclined position—the want of *verticality*—of the tube. If the tube be not vertical, the measured *height* is no index to the *weight* of the column; and unless the mercury be pure, and its specific gravity therefore constant, it would be equally

impossible to deduce weight from height. But as neither error is a necessary one, we shall consider our instrument not imperfect, through such carelessness of its artists. The second class of absolute errors cannot be avoided by the best makers, and must be corrected by the Observer. They consist of two items, and form what is called the *absolute equation* of each Barometer. The first of these items depends on a permanent physical cause—*capillarity*. On looking at any mercurial surface, within a glass vessel, any one may notice that it is *convex*—the sides being depressed. This influence of capillarity then, as exercised between glass and mercury, tends to depress the mercurial column; and, it does this the more, the narrower the tube. In case of a siphon barometer, such as fig. 1, the depression of both surfaces will be the same, so that this item of absolute error may be neglected; but in case of barometers like fig. 2, when the lower surface is much larger than the upper, the mercury will be permanently depressed, and the reading, as above described, will be too small. A certain quantity must thus be added to every reading; and it is required to determine that quantity. The researches of Gay Lussac and Schliermacher, and the analysis of Poisson, have enabled calculators to construct tables for this error. It does not depend on the diameter of the column or the inner diameter of the tube alone, but also, on the dimensions of the *meniscus* in a vacuum; so that the table has two variables as its index. The best table is by Delcros. The depression due to capillarity being thus ascertained, it is sometimes mechanically corrected for, by giving the scale a corresponding *index error*, or placing the zero point *lower than it should be*. But this correction is rarely perfect, inasmuch as it presumes the non-existence of the second item of these absolute errors,—the error of the zero point itself. Rarely, indeed, can a scale be produced absolutely free from its own index error; so that instead of an alteration of the zero point sufficing to correct the depression of capillarity, the position of that point usually involves an error itself. There is no good or accessible mode of correction in the case of the mass of barometers now in use, viz., a most careful comparison with some type-instrument, on which all the solitudes of art and science have been expended. By such comparison the *apparent* absolute equation may be obtained. II. The errors, which vary with every act of observation, are also twofold. First, however accurately the scale may correspond to its zero point, when constructed, it is plain that it must become erroneous should the brass tube on which it is engraved vary in length. But that tube expands and contracts according to the rise or fall of its temperature; and the scale can never be accurate therefore, unless when the tube is of the exact temperature it had when the scale was first cut. To remedy this source of error, the rod or tube containing the scale, was, at one time, con-

structed of materials the least of all liable to expansion or contraction—such as *wood*: now however, a metallic tube, whose rate of expansion has been determined, is adapted for all good instruments, on the principle that it is preferable to deal with a large though ascertained error, than with a small and indefinite one. It is necessary therefore to ascertain the temperature of the *scale-tube* at every observation, and to add to, or subtract from, the height as read on the scale, a quantity due to the expansion or contraction of the tube, taking as a basis its natural temperature and height. This necessity of determining the temperature of the tube, requires that a thermometer, $T T'$, be attached to the tube; and that this thermometer be read off quickly at the commencement of the process of observing.—The second cause of error is due to variation of temperature also; but to its effects on the *mercurial column*. The object of the instrument being to give the *weight* of the air by observation of the *height* of the column; it is evidently implied that the mercury remain of a *constant specific gravity*; for then alone could similar heights represent corresponding weights. Now the specific gravity of mercury is not constant, if its temperature varies: this liquid, expanding like all others, and becoming of inferior specific gravity as its temperature increases. The temperature of the mercury must be ascertained therefore, as well as the temperature of the tube: and in many of our best Barometers this is done by aid of a second thermometer whose ball is plunged amid the mercury. Often, however, it is assumed that the temperature of the mercury corresponds, or very nearly corresponds, with the temperature of the metallic tube; and that a single observation of the thermometer will suffice. The amount of correction for these two errors grouped together, is obtained in practice from suitable tables, whose indices or variables are the observed temperatures. Such the needful corrections. but errors in the result will still remain. The process of observing the Barometer is a very nice one; and only the greatest care and large practice will secure the observer against mistakes seriously interfering with the usefulness of his results, in those more delicate inquiries on which science is now entering. Hence, as we shall see below, the very high importance of *self-registering Barometers*.—Mr. Newman of London has long enjoyed deserved reputation for the structure of Barometers. We gladly notice also the excellence of the Barometers of Fortin, as now produced by M. Ernst of Paris.

Barometer, Aneroid.—A very beautiful, portable, and accurate instrument, recently invented by M. Vidi. It was introduced to the British Association in 1848, by Professor Lloyd of Dublin. The face of this Barometer, presented in fig. 1, is four or five inches in diameter; the barometric heights being indicated by the hand. Behind the face is a brass box, about $2\frac{1}{2}$ or 3 inches deep, containing the apparatus, on which the weight of the

BAR

atmosphere acts. The apparatus itself is a little complex, but its principle will be readily under-

Fig. 1.

stood; by aid of figs. 2 and 3, which are sections of the important parts of it. D D, fig. 2, is a circular

Fig. 2.

Fig. 3.

metallic case called the vacuum chamber, the sides of which are thin and corrugated, so that their elasticity is great, and therefore the readiness with which they yield before variations of atmospheric pressure. This chamber may be exhausted wholly or partly through a tube, F. In the state of exhaustion it would take the form of fig. 3. When prepared for use, however, the exhaustion is not complete; and the corrugated diaphragms take the position of the dotted lines in fig. 3, leaving between them a certain free interval along the whole interior of the chamber. A quantity of gas is introduced after exhaustion, by means of the variation of whose elasticity, at varying temperatures, compensation is effected

BAR

for the changing capacity of the case. The case or chest being 2.5 inches in diameter, the pressure of the atmosphere upon its sides or diaphragm would be about 73 lbs. were exhaustion perfect: in the actual instrument it is not more than 44 lbs. It is easy to see that, on any sensible variation of atmospheric pressure, the two sides of this metallic chamber, will either recede from each other or approach, according as that pressure diminishes or augments: and that in consequence of such receding or approach, the free stalk or rod, M, will obtain a slight motion in or out, at right angles to the face of the Aneroid. This motion is, in the first place, changed by ingenious contrivances from a vertical motion to one parallel to the face of the dial; and this last is again changed into a rotatory one—that moving the index hand—by the application of a watch chain to a small cylinder or drum. This process of change is also made to augment or multiply the original very slight motion, by aid from levers; an effort so well accomplished that when the corrugated surface moves through only $\frac{1}{100}$ th of an inch, the index hand on the face turns over a space of three inches. The only correction required for the aneroid is a slight one for temperature, detected experimentally thus:—Observe carefully its indication at any moment in the external air; remove it immediately before a fire, and heat it until the thermometer on the dial shall reach 100° ; then notice the variation of the hand: this variation, divided by the number of degrees through which the thermometer has moved, will give the correction, whether in defect or excess, to be applied for each degree of change of temperature. The extreme portability of this little instrument, and its comparative freedom from risk of fracture, give it immense advantage over the mercurial barometer in all cases—such as in measuring altitudes—where its transport is necessary; and certainly it has well stood the strongest tests as to its accuracy. Mr. Lloyd states, for instance, that he had placed one under the receiver of an air pump, and found that its indications corresponded with those of the mercurial gauge to less than 0.01 of an inch; and, within ordinary variations of atmospheric pressure, the coincidence is very remarkable:—The sum of the heights of 109 observations by the aneroid, gave in one set of experiments 3239.712 inches, the corresponding sum with the mercurial barometer being 3239.44. The Aneroid was thus in excess only 0.272 of an inch, which, divided by 109, gives for the average error, or rather discrepancy, of one observation, the very small fraction 0.00249 of an inch. Modifications and different forms of the Aneroid have already been proposed: among which are those named *Metallic Barometers*. The principle is the same.

Barometer, Siphon, Simplicometer, Portable.—Various forms of the Barometer have been proposed. One, the *siphon*, consisting mainly of a bent tube (fig. 1, BAROMETER), without a cistern,

as in fig. 2. The altitude of the column is sometimes measured at the upper surface and sometimes at the lower—the changes of position of the lower surface evidently corresponding with changes in the position of the upper one. In this latter case, correction for the temperature of the mercury may be dispensed with, as it is the *weight*, not the *height*, of the long column which is directly measured:—the position of the lower surface would be the same, although the greater part of the upper column were not mercury, but some other liquid. These *Siphons*, however, are not favourites with scientific Observers. They are subject, especially, to disturbance from an inequality of capillarity, or of the *meniscus*, when formed in *vacuo* and in the air. They are also fragile; and altogether the construction is inferior. — Another modification was proposed

many years ago by Mr. Adie of Edinburgh, and is of much value, through the extent of its range. As represented in the accompanying woodcut, it consists of a portion of permanently elastic gas, enclosed in the upper part of a tube, and separated from the external air by a fluid, which neither acts on that gas, nor is acted on by the external air. The gas employed is hydrogen; and, in the cistern, oil of almonds, coloured red by alkanet root. As the pressure of the atmosphere varies, the enclosed hydrogen expands or contracts, by proportional but large quantities; and the liquid, accordingly, either rises or falls in the tube, to which a scale is attached, through large spaces. The sensitiveness of this instrument, and its extensive scale, makes it a deserved favourite at sea; but, for delicate meteorological purposes, it is quite inferior to the mercurial barometer, in consequence, chiefly, of absorption of hydrogen by the oil. To enable the observer to correct for temperature, a thermometer is attached. *Portable Barometers*, chiefly of the siphon form, are instruments made with especial view to safe and easy transport. Very ingenious and excellent barometers of this kind have long been made at Paris and Berlin: but they are now superseded by the *Anæroid*.

Water Barometers, &c.—These are instruments quite like the mercurial: the liquid employed being water, &c. instead of mercury.

Barometer, Self-Registering.—There are two distinct functions of what are called self-registering instruments:—The *first*, to present continuously the course or flow of a changing phenomenon,—of which, without their assistance, we can learn the condition only at a few and separate moments of time. The *second*, to enable

us to avoid, by some process of *mechanical recording*, the errors inherent in every act of observation. To accomplish the first object, self-registering Barometers have been offered in various forms; but, in general, we have lost in exactness as much or more than we gained through the continuity or frequency of the record. No instrument of this kind has been produced sufficiently free from irregularities arising out of *friction* and other mechanical obstacles. Of all those with which we are acquainted, the Bryson's of Edinburgh is undoubtedly the best; the instrument marking its condition every hour on a cylinder turning regularly round, through means of its attachment to a clock. But this instrument leaves untouched the errors of observation; nay, the mode by which it provides for the subsequent measurement by the observer of the altitude or value of the marks it attains, is the weak part of it. This *second* source of error can be got rid of only in one way, by the aid of *Photography*. It is not too much to allege that the happy application of this art will ere long supersede personal observation in such cases altogether; while at the same time it affords the means of recording continuously the changes of any phenomenon in a state of *flux*, however various these may be. We do not intend to describe in this place the mechanics of this application of Photography, because these will certainly be much simplified. Suffice it, that the efficiency of the application alike to Barometric, Thermometric, Hygrometric, and Magnetic changes has been amply verified at our great National Observatory of Greenwich. The instruments in action there, were constructed by Mr. Brooke; and it is understood, that their eminent value is acknowledged, and the opinion we have just expressed fully concurred in by the Astronomer Royal, Mr. Airy. See Article PHOTOGRAPHY, REGISTRATION BY, in Appendix.

Barometer, Repeating. See Appendix.

Base. In geometry, the base of a figure means properly its lowest line, if it be a plane figure, or its lowest surface if it be a solid. In trigonometrical operations, the base is a line carefully measured between two points readily accessible, from which, by measuring *angles* alone afterwards, we may obtain the length of lines not observed. Upon the accuracy of the measurement of the base depends therefore, the value of the whole series of operations. In consequence, the greatest precautions are taken in surveys, not to neglect changes of length from changes of temperature in the measuring chain—differences of level—the spherical figure of the earth's surface, and the like. What is called the *base line*, in measuring the length of a degree of latitude (see LATITUDE), is the length marked off between the points, the inclination between the verticals at which is to be answered.

Basileon. A term of fortification, applied to a work in the shape of a pentagon inserted in the

BAT

wall of a fortress. It consists of two *faces*, which form a salient angle to the spectator outside; of two *flanks*, which connect the bastion with the *curtains*; and of a *gorge*, which separates their extremities, and by which entrance is to be obtained. The bastion usually consists of a mass of earth, surmounted with turf, bricks, or stones. It was not used till about the beginning of the sixteenth century.

Battery. Several guns playing at the same place, under cover or otherwise, are called a *battery*. The full description of the various kinds of batteries will be found in every work on *Gun-nery* and *Artillery*.

Battery, Electric.—Without entering in this place extensively into the general subject, the reader may be reminded that, in the absence of any positive knowledge of the intimate nature of electricity, it has been found convenient to suppose that the phenomena are produced by two fluids, which have a tendency to combine and neutralize each other's effects, or even altogether to disguise the ordinary evidence of their existence. In this state of union, the substance with which they are associated is said to be non-electrified. They are called the vitreous and resinous electricities, this mode of expression being now generally preferred to that of Franklin, who endeavoured to explain the phenomena by the supposition of only one fluid, which, when uniformly distributed, constituted the common or unelectrified state of matter. When in excess, as on a piece of glass that has been rubbed, the body was said to be positively, or when in defect, as in sealing wax after friction, negatively electrified. These names are respectively synonymous with vitreous and resinous in the first-mentioned hypothesis. When the prime conductor of an electrical machine is of a large size, a very considerable amount of vitreous electricity can be accumulated on it; but it has been found that, by the employment of the principle of what is called electric induction, a vastly greater quantity can be accumulated in a comparatively small space, and in a state more capable of producing many of the effects of this remarkable agent. Such is the purpose of the electric or Leyden jar and battery. The principle of induction may be stated thus:—If a good conductor be interposed between an electrified and an unelectrified body, the accumulated electricity (say the vitreous) attracts resinous electricity from the other body through the conductor, and the ordinary unexcited state is restored, or the body is said to be discharged. If, however, the interposed substance be not a conductor, then discharge cannot occur, but the vitreous fluid in the electrified body attracts the resinous fluid naturally in the neutral substance, and *tends* to draw it through the non-conductor, while at the same time it repels the vitreous or fluid similar to itself, this being a fundamental law of electric action. If now a path be opened for the escape of the repelled

BAT

vitreous fluid, as by presenting to it a metallic rod or other good conductor, it passes off, and we have the remaining resinous fluid and the communicated vitreous acting on each other by induction across the substance of the non-conductor, disguising each other's presence, and strongly tending, by their mutual attraction, to effect a junction as soon as a conducting channel shall be afforded. In this species of action, the mutual repulsion of the particles of each of the fluids is overcome, by the attractive power of the opposite fluid acting across the substance of the non-conductor, and thus a vastly greater accumulation can take place than the self-repulsive power of each species of fluid, for its own particles, could possibly permit, were it not for this artifice of causing each fluid, by its proximity, to subdue, so to speak, the other. In this state the non-conducting substance is said to be charged with disguised electricity, and the instant a conducting circuit is established, the two species join, and the discharge is effected. Sealing wax, gum lac, gutta percha, or glass, or indeed any tolerably perfect non-conductor of electricity, may be used. A thin plate is the most effective, and in order that the different points of the surfaces may act simultaneously, a film of conducting substance must be spread partially over both sides, leaving, however, sufficient space near the borders to preserve the insulation. A plate of common window glass, coated with tinfoil on each surface to within an inch of the edge, makes an excellent apparatus for the accumulation of electricity in the manner above referred to. Being rendered carefully clean and dry, it is charged by holding it by one of the corners, bringing the tinfoil of one surface in contact with the prime conductor of the electric machine in action, the finger or a wire being kept in contact with the foil of the opposite surface, to allow of the escape of the repelled vitreous fluid. This simple and effective arrangement affords a ready means of dispelling the popular fallacy regarding the Leyden jar, viz., that the form of a jar is necessary, in order that the electric fluid may be retained in it in opposition to its tendency to flow out like water. Although it is true that any quantity of electricity might be collected on a sheet of glass arranged as indicated, by sufficiently increasing its size, still such an apparatus would be cumbersome and liable to accident. It is therefore found that the form of a jar is more convenient, and glass is the substance usually preferred, the thickness being from $\frac{1}{8}$ th to $\frac{1}{4}$ th of an inch. A greater thickness than this impedes the action. Each surface has tinfoil smoothly pasted on it to within about two inches of the mouth, a cork or dry wooden lid is inserted, through which a metallic rod passes, terminated at the top by a smooth ball of half-an-inch diameter, and ending below in a chain which reaches to the inner coating of tinfoil on the bottom. The ball thus represents the inner surface, and the outer tinfoil the exterior. Be-

BAT

when these the discharge tends to take place. When a great accumulation is required, instead of using one very large and therefore thick and unwieldy jar, a combination of a number of smaller jars is preferred. To such a collection the name of Electric Battery is given. Each jar is constructed as already detailed, and they are then combined by placing the outside coatings in metallic contact with each other, and by connecting the whole of the interiors into one, joining all the balls by means of chains or brass rods, or more simply perhaps by binding the whole of the rods as they ascend from the interior of the jars, so that they may meet—and on the joined extremities placing a ball, which thus represents the whole of the interior surfaces. A battery composed of six jars, each exposing two square feet, is sufficient for the exhibition of most of the effects of accumulated electricity. When powerfully charged, which it will be by about a hundred turns of a good machine, it should be handled with caution, care being taken that no part of the body be brought near the ball. If this be attended to, the exterior surface may be freely touched. The chief secret in the successful management of this, as indeed of most pieces of electrical apparatus, is, that it be rendered perfectly clean and dry; indeed it is generally essential that each jar should be taken separately and rendered warm by being held with a turning motion for a few seconds over a fire or a good flame, just before being used. It is proper also, to prevent disappointment (which is so frequent), that a pithball electrometer should be attached to the battery, to indicate, by the amount of its divergence, the progress of the charge.

The annexed cut represents a battery, with

an electrometer indicating the charge, and a jointed discharger need for passing the charge through the substance of an egg, which lie on the chain from the outer surface. One ball of the discharger is placed on its upper surface, while the other is brought up to touch the ball from the internal coatings, when the spark flies, and the discharge is instantly completed.

Battery, Galvanic or Voltaic.—The apparatus

BAT

to which this name is given must be regarded as one of the most curious and remarkable of human inventions. The exhibition of its effects scarce fails in exciting, in the thoughtful observer, admiration of the genius which has constructed, from the apparently inert and lifeless matter of the earth, combinations of power so strange and subtle, an instrument so potent in the laboratory of the philosopher, and now so useful in the processes of art. Of the theory of the Galvanic Battery little can here be said, nor indeed could it be of value, as all that is known regarding it rests on hypotheses in themselves full of doubt. Without entering into speculations as to the electric relations of the atoms of matter, it may be stated, as tolerably well ascertained, that there is no case in which chemical change occurs among the constituents of any substance, without a disturbance of their electrical state. In some, nay in most cases, this disturbance would altogether escape notice, were it not for certain precautions taken expressly for its observance. For instance, say that we dip a piece of metal, such as brass, into diluted sulphuric acid, in a glass vessel; the metal would be dissolved, and we should not be sensible of any electrical change. If, however, the containing vessel were tin or iron instead of glass, then, on bringing the edge of the dissolving brass in contact with the edge of the vessel, a spark of light would instantly give notice of the passing energy. To this the name of Galvanic Action has been given, and the agent is called Galvanic or Voltaic Electricity. That it is common electricity in a modified form has been proved, and the difference between the two has been compared to the difference between a mountain rivulet, or rushing cascade, rapid and powerful though small in quantity, while the other, the galvanic current, resembles the rolling waters of a broad and deep, though slowly moving river, the frictional electricity excelling in *tension*, while the voltaic current far exceeds it in *quantity*. In the absence, hitherto, of certainty as to the intimate nature of the actions in question, such phrases as Galvanic Current, Positive and Negative Pole or Electrode, &c., must be conventionally used till a more correct nomenclature shall emerge from advancing knowledge. It will be sufficient here to state as an ultimate fact, that when two different substances, together and without contact, are immersed in a substance, generally a liquid, which chemically acts on both, the two are thrown into opposite electrical states; that which is most energetically acted on becoming negative or resinous, while the other becomes, with reference to it, vitreous: and further, that these actions are most powerfully observed when the chemical action is one of oxidation, and both substances are good conductors. Though it is important to keep in view this generality in these actions, still it is known that metals undergoing solution in acids are most favourable for the energetic exhibition of the galvanic phenomena. In

the choice of the pair of metals to be put together to form the combination, it must be kept in view that if both are good conductors, then the more energetically and rapidly the one is acted on by the solution, the greater is the evolution of electricity, this being called the generating plate, and the more the other resists the action of the liquid, the greater also is the energy of the combination. The one least acted on is called the conducting plate. The combination of two such plates is called a galvanic element, the most common being copper and zinc, immersed in a solution of one part of water, from $\frac{1}{10}$ th to $\frac{1}{5}$ th of sulphuric acid, according to the energy required, and $\frac{1}{10}$ th of nitric acid. When such a pair is composed of plates exposing many square feet of surface, great energy is evolved. A wire connected with the copper is called the positive pole or electrode, while the same with reference to the zinc is called the negative pole or electrode. Any substance to be subjected to the action is placed between the poles. The current is said to pass. Metallic wires are heated to redness or dissipated in vapour, vivid sparks are seen, pieces of charcoal are heated to intense whiteness, producing what has been somewhat erroneously called the electric light. Powerful magnetic effects are likewise induced in coils of wire. But some of the most important actions of the current cannot be evolved by this apparatus of a single pair, however large. It is deficient in tension, and can only traverse very good conductors. To give impetus or force to the current, a combination of single galvanic elements into a battery is necessary. Before referring to the modes in which such combinations are formed, it may be as well to attend a little more minutely to the different kinds of single elements which are used. They may be divided into those of one liquid and those of two liquids. Of the first is that, the most common and generally useful, of a zinc and copper plate of about equal thickness, and separated by an interval of about half-an-inch, the exciting liquid being one part of water, $\frac{1}{10}$ th of oil of vitriol, and $\frac{1}{10}$ th of nitric acid. This arrangement is much improved and rendered more economical, by the amalgamation of the zinc plate, which is readily accomplished by rubbing its surface with metallic mercury, while it is moistened with one part of sulphuric acid to eight of water. By this means, first suggested by Mr. Kemp of Edinburgh, the surface of the zinc plate is kept bright and free from oxide, while its substance is only wasted down by the acid during the time that the current is actually being used, all waste in the intervals being thus avoided. The modification usually called Smee's Battery consists of an amalgamated plate of zinc placed within half-an-inch, one on each side, of a thin silver conducting plate on which

platinum, in a fine state of division,

has been precipitated. The nitric acid is omitted in the exciting liquid. The superiority in this case is supposed to consist chiefly in the freedom with which the hydrogen escapes from the platinum surface of the silver, as contrasted with the manner in which it clings to the plates of the copper battery. In each of these cases of single liquid elements, the evolved current, though energetic for the first few minutes after the fresh liquid is poured on the clean metals, soon begins to diminish, and in general, in the course of fifteen or twenty minutes, it is reduced to a mere fraction of its first force, even though the acid in the solution should be nearly of its original strength. One main cause of this has been the deposition of oxide of zinc on the conducting plate, and the evolution of the hydrogen has, during the whole process, acted as an opposing process, or, at least, loss has been occasioned by the neglect of the opportunity which the hydrogen might afford of causing a deoxidizing process on the conducting plate, thus rendering it more opposed to the generating plate, where oxidation is proceeding. To keep the zinc liquid from touching the conducting plate, to substitute for it on this latter plate a liquid capable of undergoing deoxidation by the hydrogen, and at the same time to allow much contact of these two liquids with each other as to admit of the current passing, are the objects to be attained. Such are the ends served by the constant battery of Prof. Daniell. A rod or cylinder of amalgamated zinc is introduced into a bag made of an ox gullet or bladder, or even of closely woven cloth, or, filling them, unglassed porcelain, in the form of a cylinder closed at bottom. The zinc cylinder &c., enclosed in its envelope, is immersed in a cylindrical vessel of copper, so much larger as to allow a space of half-an-inch clear all round between them. Into the copper vessel is put a saturated solution of sulphate of copper, with the addition of $\frac{1}{10}$ th of sulphuric acid, and into the envelope of the zinc is poured the usual exciting liquid formerly mentioned, of sulphuric acid and water. When the wires from the copper and zinc are joined, the action commences. The water next the zinc is decomposed. Its oxygen oxidates the zinc, which is then dissolved by the sulphuric acid, forming the sulphate of zinc, which remains in solution, and is prevented by the diaphragm or envelope from touching and contaminating the copper, while its hydrogen passes through the moist envelope, and, coming in contact with the sulphate of copper, decomposes it, reducing the metallic copper on the surface of the copper cylinder. The sulphuric acid passes through to attack

BAT

the zinc, affording a renewal of acid for continuing the action. This apparatus, when properly constructed, keeps in an energetic state for hours, and is hence called constant. Subjoined is a drawing of one of its forms.

Each element in Grove's Battery is constructed on a similar principle. In this case platinum is used as the conducting plate. It is, from its expansive nature, used only in thin sheets, and is placed in strong nitric acid, in the interior of a thin flat trough of unglazed porcelain, the organic diaphragm, though otherwise preferable, being in this case inadmissible. One amalgamated zinc plate may be placed on each side of the porcelain trough, and the whole placed in a vessel of any convenient size, containing the usual exciting solution of sulphuric acid and water. In this case the hydrogen deoxidates the nitric acid and forms water, while the nitrous acid so produced remains dissolved. After a time, however, it begins to be evolved into the atmosphere, and at last the nitric acid fairly enters into ebullition. This combination is of great energy and constancy; it is, however, in its first construction, costly, and is liable to accident. If cylinders of carbon, the best being that left by sublimation in the retorts of coal gas works, be substituted for the platinum, we have the element usually known by the name of Bunsen's. Square prisms of the coke can easily be cut by a marble cutter, and answer well. A piece of copper wire is wound round their upper part as the conductor, and they are inserted into the nitric acid. Great care is necessary in washing them after each time of using, otherwise the copper is oxidated, and the current ceases to pass. A battery of this kind may be constructed for £2, which, for equal efficiency in platinum, would cost £30.

Another excellent combination of two liquids is that of Callan, or the Maynooth element, as it has been called. The conducting plate is made of the form of a cylindrical vessel, and is of cast iron. The amalgamated zinc cylinder is placed in a porous cell an inch larger than itself, for containing the sulphuric acid and water, one of acid to eight of water. This is then placed in the cast iron cell, which is so large as to leave about half-an-inch all round of space, for containing the second liquid, which is composed of strong sulphuric acid, and a drachm of nitrate of potash to the ounce of acid.

Such are the chief modifications of the galvanic element, and while undoubtedly that of Grove is the most powerful for its bulk, that of Callan, for its energy, is the most economical.

All the different species are easily made into batteries, by the combination of a greater or less number of single elements into one arrangement, which is done by connecting the generating plate of one element with the conducting plate of the next, and so on. For the communication of what is called the shock, to the human body,

BEL

from 60 to 100 pairs of the single liquid copper and zinc combination, each plate being three or four inches square, are necessary. This would also be sufficient to exhibit most of the effects of chemical decomposition, and the heating power of the current, on thin metallic wires and leaves, as also for the feeble production of the electric light. About a dozen cells of Grove's two liquid combinations of a similar size would produce the same effects, and three dozen elements of Callan, each exposing half a square foot of zinc, is sufficient to produce a tolerably brilliant light when transmitted through points composed of the gas coke, formerly mentioned, and brought to touch each other as poles.

The Galvanic Battery, as is well known, is now an instrument of great practical use in the Electric Telegraph. For this purpose the form most generally preferred is the simple copper and zinc plate, each about three inches square, immersed in a cell of earthenware or gutta percha containing river sand moistened by the usual diluted sulphuric acid. This arrangement is called the sand battery. It is steady in its action, and, once arranged, keeps in force about a week without requiring the acid to be renewed on the sand. In the offices of the Edinburgh and Glasgow Railway, a battery of about 100 such plates is used for the transmission of signals from one city to the other, while in the arrangements of the Electric Telegraph Company, batteries of about from 1,000 to 2,000 such plates are used, owing to the great distances over which the signals must be sent. In this respect, however, much depends on the state of the weather and insulating condition of the supporting posts for the wires, and also on the diameter of the wires themselves. On this curious and interesting subject, however, the article TELEGRAPH is referred to.

Since the prospect of a greatly extended use of the Galvanic Battery as an illuminating agent has presented itself, a view of the process depending on the generality of the connection of the galvanic excitement as an attendant on chemical action has led to important results. It has been proposed to employ only such substances for batteries as will produce, as a residue, materials of commercial value. Hopes are entertained that, during the preparation of pigments, and in many otherwise necessary processes of chemical manufactures, by proper arrangements vast amounts of electricity now uselessly allowed to waste will be evolved, in a form fit for the production of light, or the development of other actions of value. The mere mention of such effects suggests sources of power for the benefit of mankind which cannot be contemplated with indifference. Strange that such results should have flowed from the convulsion of a decapitated frog!!

Bear, Great and Little. Two constellations in the Northern Hemisphere. See URSA MAJOR and MINOR.

Bell. A musical instrument in which the

BEL

vibrations of the metals, when struck, are the direct cause of the sounds.—(See ACOUSTICS) We can easily understand, according to the laws of acoustics, how bells can be constructed, from which the same impacts will produce different notes. Upon this depends the machinery of what are called musical bells, which play at certain hours of the day. The material of which bells were originally composed was in all likelihood, merely cast-iron. That now used is a compound of 80 parts of copper, and 20 of tin. This is the theoretical proportion; and Indian gongs are made exactly in accordance with it. In ordinary bells the proportion of copper remains the same, but some lead and zinc is substituted for part of the tin. This alloy is very remarkable for its great elasticity, and therefore its great capacity of sound.

Bell, Diving. It is frequently desirable to raise objects from the beds of rivers or lakes, or from the sea-bottom; *e. g.* the processes of fishing for pearls, sponges, corals, and other sub-marine products. Often again, it is needful, as in laying the foundations of piers, or in removing sunken rocks from a channel, that we should possess the power of remaining under water for a considerable period. Man does not possess this power naturally, so that he must supply it by suitable contrivances. The longest time during which a practised diver can remain under water is about two minutes. Ordinary persons are not able to support such a condition for more than half a minute. Those half savage tribes that are accustomed to water from their infancy, seem to become semi-amphibious, and can support immersion for a much longer time. The inhabitants of the South Sea Islands afford a good proof of this. A most extraordinary instance is related, on the authority of Kircher. In the time of Frederic, King of Sicily (about the commencement of the 14th century), lived a celebrated diver, by name Nicholas. He was surnamed, for his powers, *Pesce* (a fish). He had from his infancy been used to the sea as a fisher for corals and oysters. He came to be so accustomed to it, that he had been known frequently to spend five days in the waves, catching fish and eating them raw, for his subsistence. He was in the habit of carrying letters frequently between Calabria and Sicily (a very coarse passage, by the way). His hands and feet grew ultimately webbed, like the feet of a *goose*, and he became capable of inhaling, at one breath, enough of air to serve him for a whole day! His very glorious career was unfortunately cut short by the inconsiderate curiosity of the king. His Majesty sent for him to the palace; and when Nicholas had been found—from his unusual mode of living, this was not so easily accomplished—he came. Frederic desired him to explore the bottom of Charybdis, which, though unwilling, he ultimately undertook, upon the renewed solicitation of the King, and his flinging a golden cup into the

BEL

whirlpool, which was to be the diver's own, if he could find it. He dived, and after three quarters of an hour, rose with the cup. He gave an account of the whirlpool as being lined with jagged rocks, to which clung a strange polypous fish, that stretched out its fibres in the most frightful way to catch him. Frederic, not perfectly satisfied with the account, requested Nicholas to re-descend. Nicholas allowed himself, by the prospect of a still larger cup, to be over-persuaded—dived, and perished. Every reader of German poetry will remember Schiller's exquisite ballad, the *Diver*, which founds on this legend.

There are two prime requisites in an apparatus for diving—the constant supply of air, and the protection of the body of the diver from too great pressure.

The first method adopted was the very simple one of letting down a heavily weighted bell vertically into the water—the diver sitting in the interior. As it descended, the air got overpressed and the water rose in the bell, but never to the top. The man sat in the top, above the water mark, and if the bell was large, could so remain for about an hour. The air became gradually poisonous by his continued respiration, and he had to be taken up.

Several evident defects occur in this instrument. The man is always kept by it, at some length from the ground. He goes through a process of inspiration, of air constantly deteriorating; and several similar objections might be pointed out. Dr. Halley's diving-bell was invented to remedy those evils. It was of wood coated with lead, and having at the top a strong glass window, by which light might be admitted to the diver below. In order to supply air, a barrel was taken with an open hole in the bottom, and a weighted hose, hanging by and fitting into a hole at the top—so weighted that it would naturally hang below the bottom of the barrel. The barrel is let down vertically by weights, and the hose is caught by one of the men in the bell, who lift it up and let the air escape from the barrel into the bell, sending it up when empty. A cock lets off the carbonic acid formed by the breathing of the diver, when the air in the bell gets filled with it. The bell is thus kept always filled with air; and the air kept constantly pure.

Two practical difficulties yet remained. When the bell descended, on a rough surface, it was apt to be caught on some rock and tilted over from its vertical position—the air escaping, and the divers perishing; and again, the whole management of the bell depends upon the people above, so that if the rope was broken, or rubbed against a stone, the same fate awaited them. To obviate the first difficulty, Spalding's diving-bell has a heavy weight attached to its middle by a rope which can be raised or let down as convenient: it is let down the moment that the bell touches a rough spot; and then, resting on the ground, it relieves the

BEL

bell from its weight, and enables it to rise up from the obstacle. To overcome the latter difficulty, the bell consists of two cavities instead of one, the first or upper one having lateral holes by which superfluous air may escape, and when the bell goes down, this cavity is filled, by the water pushing out the air. When the diver wishes to ascend, he opens a small screw in the lower chamber, which, admitting air, pushes out the water from the upper chamber, so lightens the bell and makes it rise. Triewald, a Swedish engineer, introduced further improvements. At the bottom of the sea, the light is scanty, and Halley's contrivance of a strong glass window in the top, or Spalding's, of one on the sides, did not give so much as was occasionally desirable. Triewald made his bell of copper, tinned over in the inside, so as to give a very strong reflecting power, further increasing this by placing three strong convex lenses near the top of the bell. He also added a set of chains, suspending a platform, so that, when not at depths rendering the pressure inconvenient, the diver might stand upon it with his head just above the water. He obtained in this way the air purer than he could, if sitting quite dry. Triewald arranged also, a coil of tubes inside, by which, even if sitting, the diver might breathe the air nearest the bottom of the bell.

Halley noticed a very curious and interesting phenomenon in his diving bell. While holding his hand in the light coming through the window at the top, he found the back of it appear red, while the palm of his hand, held downwards, facing the water, and illuminated chiefly by the light reflected from it, was green. The explanation was given by Newton. The sea-water transmits the red rays of the spectrum most readily, and reflects most copiously the violet.

Bellman. One of the Asteroids. For elements, &c., see ASTEROIDS.

Bellows. When we wish to direct a stream of air against any object, an instrument is used called the Bellows. It is of various constructions, but the principle in all cases is very much the same. The reader will readily understand it by taking a pair of common bellows in his hand, and commencing to use them. The bottom lid, or plate of wood, is supplied with a valve opening only inward, and shuts when the bellows are not in use, by its own weight. Closing also the pipe of the bellows, is a valve, which opens outward only. When, then, he pulls asunder the plates of the bellows, the air attempts at both places to issue, in order to supply the empty space thus made. The valve at the mouth, opening outward only, will be shut by this rush of air; the valve in the bottom plate, opening inward, will admit it. When enough air has been admitted, he squeezes the plates again together. The air seeks to avoid the compression by escaping through the valve, and the rush of air closes the bottom valve, which does not open outward, and opens

BEL

the valve at the nozzle of the bellows. The air which is thus taken from the ordinary atmosphere by which the bottom valve is surrounded, is directed with considerable velocity through the nozzle to any point whether we desire to transmit it.

In using the bellows for large furnaces, it was found that the inconstant blast thus supplied was a source of considerable loss of advantage. The fire receiving the current of air burned violently for the moment (oxygen being supplied as fast as consumed), and next moment lost much of its heat. It was impossible thus to use the bellows, when it was desired to subject a body to a constant heat. To prevent this, two bellows were for some time employed—one of which was filling with air while the other was exhausting it. This secured the desideratum of a permanent supply of air, but it did not sufficiently secure a uniform supply—because the air emitted at one part of the compression of such bellows could not always be the same in amount with that emitted at another. The instrument which we engrave is perhaps the best and the simplest of those employed for the removal of this defect.

z p is a piston wrought generally by a steam-engine—where convenient by a water-wheel. *u* and *u'* are the places where the air enters by pushing the valves which open inwards, but not outwards. At *u'* and *u'* there are valves which open outwards (communicating with the tube *o*), but not inwards, so as not to permit the air once collected there to drive back again. When the piston descends the valve *u* admits air, and the valve *u'* expels air previously admitted into the under part of the cylinder. When the piston ascends, *u* admits air, and *u'* expels that admitted in the descent. Air is thus collected in *o*, and emitted at a uniform pressure, and with uniform velocity, therefore, by a stop-cock or a valve in the

pipe o, leading to the object upon which the air is to be driven.

One objection to the process described cannot fail to be evident. It is this—that the cold air constantly supplied will be a constant source of cooling to the furnace. It is indispensable to the continuance of the flame that air should be supplied; and as many operations in the arts require the highest temperatures that can be reached, it became necessary to destroy this effect of the admitted air without destroying its power of supporting combustion. The method adopted—the *Hot Blast*—requires merely the heating of the air before admission into the furnace. In this way there is a constant temperature preserved, as well as a constant supply of oxygen. The Hot Blast is now almost universally adopted, as it affords this very important advantage, and that with greater economy of fuel, than, with the older forms of Bellows, was possible for the furnace. The details of apparatus, &c., will be found in works on *Metallurgy*.

Belt. See SATURN and JUPITER for an account of the planetary rings and belts.

Betelgeuse. The brightest star in the constellation Orion. It is of the first magnitude.

Binocular. See TELESCOPE and VISION.

Binomial (Technical.) A Binomial is an Algebraic quantity composed of two parts separated by the signs of addition or subtraction. The theorem for the development of binomials—the *binomial theorem* of Newton, which is engraved on his tomb, as being one of the most beautiful of his discoveries, we merely give here, without proof. A demonstration of it will be found in any good elementary work on Algebra. It is this:—

$$(a + b)^n = a^n + n \cdot a^{n-1} b + n \cdot \frac{n-1}{2} a^{n-2} b^2 \&c. \dots n \cdot \frac{n-1}{2} a^{n-m-1} b^{m-1}, \&c.$$

Bisextile. The natural measure of time in small portions is the interval between two successive returns of the sun to the meridian. A measure no less natural than the day is for the smaller portions, is provided by the year for the larger portions. Upon the civil year, the interval between the sun's appearances on the same point of the ecliptic, depend the variations of the seasons. The year contains 365 days, 5 hours, 48 minutes, 50 seconds. Suppose, then, the year and the day to begin at once this year—next year will commence at 5^h 48^m 50^s A.M.; and when we calculate the number of days from the commencement of the year for any purpose, we should get confused between these and the ordinary day from meridian passage to meridian passage. The year must thus somehow be got to be considered

for social purposes as commencing with the day, or very great confusion will arise. Julius Cæsar saw this, and appointed that in every fourth year there should be two days both reckoned as the 24th Feb., and that the months should stand as we have them now—February by this reckoning having really every fourth year, 29 days, and being considered to have only 28. This gave for three successive years 865 days, and for the fourth 866. Cæsar thought that thus a cure would be provided for the evil, and that once in every four years, the commencement of the physical year and physical day would coincide. The 24th of February was called “sextus Calendas Martii,” and hence the year which doubled this day was called “bis sextus Calendas Martii,” and we call it *bisextile* or *leap year*. This idea of doubling the day is legally affirmed by a statute of our own Henry III. Had the year been 865 days 6 hours long, Cæsar's anticipations would have been verified; and though it was nearly so, yet the little errors, constantly accumulating in the same direction, threatened serious inconvenience—tending to make our year commence in spring instead of winter, and destroying the value of the weather maxims for the month, on which the farmer and many others rely. When Pope Gregory XIII., in 1582, reformed the Calendar, the leap year had gone on about 11 days before the true year, and, in consequence, there seemed to be a slow retrogression of the seasons. To prevent this, and to render the positions of the seasons permanent in the year, except so far as physical causes might operate, it was enacted that so many days should be passed over, and the mischief already done thus repaired. Provision was also made against new danger of a similar sort. It was decreed that each century, which is naturally a leap year, should be an ordinary year, except those centuries the number of which should be a multiple of four. The effect of this was that 1600 was a leap year—that 1700, 1800, 1900 are not, although divisible by four—that 2000 is, and so on. The average year thus procured is 365 days + $\frac{1}{4}$ day (due to leap year)— $\frac{3}{80}$ (due to the three years in the 400, which ought to be leap years). This would give a year of 365 days, 5 hours, 49 minutes, 12 seconds. The correction requisite to reduce to a true year would be 22 seconds, and there would not be an error of a day therefore, for $\frac{24 \times 60 \times 60}{22}$ years, or

3927 years. If it be further enacted, when the occasion calls for it, that each 4000th year shall be an exception to the exception to the rule of leap years, a similar calculation would show the error, per annum, on an average to be $\frac{2}{3}$ of a second, and an error of one day would not occur in 216,000 years.

Black. The absence of all capacity of reflecting colour constitutes a perfect black. See COLOURS.

Block of Pulleys. See PULLEY.

Blue. One of the seven primary colours. See COLOURS.

Bode's Law of the Distances. This law, as it is termed, expresses a very curious relation among the distances of the several planets of our solar system from the sun; and of the satellites from their primaries. It is wholly empirical, i.e., we know no physical origin or cause for it; nevertheless, and notwithstanding the existence of exceptions or irregularities, it assuredly does point to some conditioned arrangement in our system.—I. With regard to the planets and the sun, the law may be presented as follows:—Write the names of the planets in a line, and under each place the number 4. Beneath the 4 under Mercury place 0; beneath the 4 under Venus write 3; beneath the 4 under the Earth write twice 3; beneath the 4 under Mars four times 3; then eight times 3, and so on. Add their several columns as under:—

Mer.	Ven.	Earth.	Mars.	Ast.	Jup.	Sat.	Uran.	Nept.
4	4	4	4	4	4	4	4	4
0	3	6	12	24	48	96	192	384

4	7	10	16	28	52	100	196	388
3.9	7.3	10	15.2	27.4	52	95.4	192	300

The numbers in the lower line are the actual distances of the p'ants from the sun, on the scale that the earth's distance is 10. The general conformity is too great to result from accident. The existence of the Asteroids at distance 27.4 was predicted by Olbers, through consideration of Bode's Law, because of the gap between Mars and Jupiter. The grand breach of the Law is in the case of Neptune, a breach which might be explained if we knew the cause or physical origin of the Law itself.—II. A principle of order quite corresponding, although in its indices somewhat different, may be traced in the only two groups of satellites with which we are yet fully acquainted. First, with regard to the satellites of Jupiter. The constant number here is 7; the number to be multiplied, 4; and the multiplier, 2½. Notice the correspondence as below—the Roman letters indicate the satellites:—

I.	II.	III.	IV.
7	7	7	7
0	4	10	25

7	11	17	82
---	----	----	----

True dist. 6.9 11 17.5 81

Secondly, as to the satellites of Saturn. The constant number in this case is 4, and the other parts of the series very simple, viz.:

I.	II.	III.	IV.	V.	VI.	VII.	VIII.
4	4	4	4	4	4	4	4
0	1	2	4	8	16	32	64

4	5	6	8	12	20	36	68
---	---	---	---	----	----	----	----

True dist. 5.1 6.2 7.9 11.1 25.7 33 74

There is considerable irregularity in case of the last three satellites; but is it not some compensation, that the lately discovered satellite, *Hyperion*, or the *seventh*, might have been suspected to exist, as well as the Asteroids, because of the gap between the sixth and eighth, as indicated by this Law?—Of the satellites of Uranus it would be premature at present to conclude anything.

Boiling. See EBULLITION.

Bomb. A hollow globe of iron filled with powder, shot off from a mortar, and bursting by aid of a fusee, which is lighted when it goes off, but—being made of slowly consuming paper—does not reach the powder till the bomb falls. Bombs are generally ten, twelve, or eighteen inches in diameter. *Luminous* bombs are used to illuminate, or serve as signals. The invention of bombs is claimed for the Venetians as early as 1376, but other authors name Malatesta, prince of Florence, as the inventor.

Bootes. (Boûs, an ox). The herdsman. One of the ancient constellations. It is frequently called Arctophylax by the ancients (the guard of the bear). Bootes is represented as a man with a club in the right hand, holding two dogs by a leash in the left. Arcturus, of the first magnitude, is the principal star.

Boscovich's Theory. A remarkable speculation by an illustrious Italian, concerning the ultimate constitution of *Matter*. As it has frequently and profoundly affected the structure of physical theories, it is right to advert to it here. Looking at matter as resolved into its ultimate Atoms, Boscovich imagines that each ultimate Atom may exist to any other Atom in various relations; the actual relation in which they do exist towards each other, depending chiefly on the interval between them.

The curious subject is best illustrated by a diagram. Let there be two atoms, A and B. At great distances these are affected towards each other by the attraction or affection termed gravitation; which affection, increasing as B approaches A (within sensible distances), may be represented by the curve above the line

from B to B'—the *ordinates* of which, indicating the force of the attraction, increase, according to the well-known law, as B approaches A. Suppose that at B' terminates the space of sensible distances, and the purely atomic forces begin to act. These atomic forces cannot be all attractive; nay, the ultimate one, between B' and A', must be a repulsive one, as represented by a curve below the line AB; for, if it were not, the two Atoms might be made to coincide, or, what

is the same thing, matter would not be *impenetrable*. But between B^v and B' there may be not one transition only, but several, from attraction to repulsion; as hypothetically indicated by the curve in the diagram. At any distance at which the curve is above the line AB , the two atoms will be mutually attractive, and the body they form will, according to Boscovich, be *solid*. At any of those distances when the curve is below the line, the particles would repel each other, and, according to Boscovich, constitute *gas*, or permanently elastic fluid; while, when the second particle is at B' , B'' , B''' , &c., they would be to each other in a condition of indifference, and would thus constitute a *liquid*. The Italian philosopher presented it as the ultimate aim of physical inquiry to detect all the windings of this hypothetical curve, and define the nature of its branches. One thing his conception would indicate as *possible*, viz., the transformation of one apparent description of matter into another, *independently of chemical change*. For instance, if the two atoms, in the different positions of AB^v , AB^v , AB'' , AB''' , and AB' , constitute *liquids*, these could not be the *same liquids*; so that *transmutation* might be effected through mere change of relative position; and so as to those various positions, constituting solids and elastic fluids.

Boyle's Law. See MARRIOTTE.

Brachystochrone. The name of the curve connecting two points along which a body descending would fall most rapidly. The *cycloid* would be such a curve if there were no resistance of Air. John Bernouilli first proposed the problem of the Brachystochrone in 1696.

Breast Wheel. See WATER WHEELS.

Brewster's Law. The optical law, generally so named, is this—the tangent of the angle of polarization is equal to the refractive index of the polarizing material. This requires manifestly that the line of the reflected ray, when polarized, should be perpendicular to that of the refracted ray. There are several other optical laws discovered by Brewster, and passing current under his name. They have generally been merged in higher laws.

Bridges. The principles upon which ordinary bridges must be constructed, in order to secure their stability, have been already given in the article ARCH. Certain data there referred to—such as the strength of the wood or iron, or stone, of which the mass of the bridge is composed, to resist the strain made by the weight of the parts above it, and by the loads passing over the bridge—are discussed under STRENGTH OF MATERIALS. We shall in this article give a brief account of some points connected more with the practical art of bridge-making than with the theory of bridges, but still depending upon that theory and illustrating it.

Bridges are either fixed or moveable. The latter are sometimes—as drawbridges—con-

structed on the ordinary principles of the fixed bridge. They, in fact, are fixed bridges, but one part of their mass, instead of resting, as usual, on immovable props in the earth, is connected with it by props which are jointed to such immovable portions, and in which the jointing may be removed as occasion requires. What are called flying bridges, floating bridges, bridges of boats, &c., depend upon quite other principles, and are really altogether different in character from the ordinary bridge. They are boats of a peculiar construction merely; fitted with contrivances like the gangway of a steam-boat, which they carry about with them, and apply easily to shores of any height; thus affording ready passage from these shores to the boat. They are, in fact, mere ferry-boats, with gangways attached, sometimes having a smooth deck, with no sails or rigging, and constituted by nailing planks above two or three boats placed together. They are generally drawn across the stream by pulleys, and ropes fastened over it.

There are three descriptions of pier bridges. These are the ordinary bridge with piers, the suspension bridge, and the tubular bridge.

Considering then the *fixed* bridge, and proceeding in the order of their construction along its various parts, we shall understand where the mathematical principles of the theory of arches must be applied, and comprehend generally, the other principles upon which the art of bridge-making rests. In choosing which kind of bridge ought to be thrown over a particular space, there are certain evident considerations to be attended to,—for instance, the kind of traffic for which it is needed. Thus, a suspension bridge, admirably adapted for foot passengers across a wide channel, would vibrate too much if locomotives were to pass over it. Again, for example, a bridge over the Clyde must be so constructed that ordinary boats can pass one another beneath its arches; and this will require a somewhat wider arch than might have been found otherwise desirable. For such ends suspension bridges are admirably adapted—giving the whole width of channel, and not affording any obstruction to free passage, if the boats can lower their masts. Further: where we have a channel too wide for an ordinary pier bridge to be thrown over it without great difficulty and enormous expense, and too deep to permit us to get readily at the foundations of our piers; and also requiring that navigation of all sorts be permitted freely to pass below, even where the masts cannot be lowered; and demanding, further, that locomotives pass over it, we are driven to the construction of a *tubular bridge*. The nature of the soil, too, on which the foundations of piers must be laid, requires to be known, as a first element of the calculation. If we cannot secure such a soil near the point where we wish to construct our bridge as will suit our purposes, we have either to obtain an artificial foundation, by gratings and other contrivances,

or are driven to the use of a suspension bridge. Still farther, it is a point of importance to consider the exact position of the bridge, with reference at once to the soil at its two extremities, and to the convenience of traffic. Where, for example, a bridge is to be thrown over between the mouths of two streets, both ending at the water-side, we have no choice; and if the line between them be oblique to the course of the water, the bridge must be oblique also. Where choice is left, we should never construct a bridge inclined to the line of the current. The reason is sufficiently evident. The whole value of a pier bridge depends upon the stability of the piers in their position. Hence everything that can bring unnecessary strain on these piers must be avoided. But, an oblique current, as in the

first figure in figure 1, would strike against the pier, not as in the second, with the force of the mass of water, $c\ c'$, while the other water flowed along the side of the pier and through below the arch quietly, but with the force of the additional mass cc''

Fig. 1.

super-added. Hence, with such an obliquity there would be, in addition to the pressure of the superincumbent weight of the bridge and passengers pressing on the pier, and the concussion due to the rush of water beneath striking on the pier, and of the same width as it, also the concussion due to the mass $c\ c'$ to be sustained. Not only would this affect the pier directly, but the violent repulsion of so large a mass of water, $c\ c\ c'$, would produce eddies about the pier, and these tend to undermine the foundations upon which the pier rests.

Sometimes, however, in spite of these objections, oblique bridges become advisable—for example, when we cannot obtain otherwise a good foundation, and can thus obtain one on rock—always the best for such a structure. Practically indeed the objection of greater expense from the greater length is the principal one, for most bridges on a tolerably good foundation will support a rush of water many times as great as that to which the front of the piers is usually exposed.

We have spoken of the piers in the water. These are the sources of greatest difficulty and danger in the formation of bridges. To bridges placed over a road or narrow street no piers are necessary except at the extremities; when a line of railway for example crosses a dry road, piers are far more easily constructed than in case of the ordinary bridges.

The form of the arches itself, is of inferior consequence. Many bridges have been swept away from the effects of the water in undermining their piers; while but few accidents have resulted from the adoption of arches not scientific-

cally constructed. We can readily understand, moreover, how expensive a proceeding it frequently must be to find a good foundation for piers, in the middle of a rapid and tolerably deep current. The workmen cannot work under water well; or if, by the diving-bell, they do work under water, it is slowly and laboriously. Another difficulty also presents itself very frequently in the soil in the beds of rivers—often consisting of a light, loose, sandy material, on which it is unsafe to rest any substance which will press heavily upon it. In these cases it is usual to create a sort of artificial foundation. The present ordinary mode is by what is technically called a *coffer-dam*—a hollow space formed by a double range of piles, with clay rammed in between. Hence, it is a prime object with the engineer to lessen as much as possible the number of piers.

Piers have an unfortunate tendency, also, to catch floating wood, ice, &c., drifted down by the stream, and so to submit the mass of the bridge to more violent shocks, and to impede the navigation of the river.

The Putney, and Battersea, and Vauxhall Bridges over the Thames, afford examples of all the clumsiness of appearance, and practical inconvenience of the numerous piers that were once customary—besides having this added to their list of faults, that, being in a navigated river, they impede the passage of boats, and have thereby frequently proved sources of extreme danger. The more modern construction of Southwark and New London Bridges displays, in its striking contrast, very forcibly the position which we have been maintaining.

Sometimes—indeed, pretty frequently, the danger arising from the use of too narrow arches accrues to the bridge itself, as much as to the passengers below it, by narrowing the effective passage way of the stream. But as the same volume of water as before requires to pass where the bridge is placed, the water must flow with much greater velocity through the bridge; that increase increasing with the increasing space occupied by the piers. But this increase of the velocity of the water tears a large quantity of soil away with it, and deepens the stream. An undermining of the foundations of the piers takes place; and careful and sound construction alone can check this.

A bridge of Smeaton's construction at Hexham was swept away on the occasion of a violent flood, partly in consequence of this defect. The immense sheet of water, whirling down trees and stones, caught on the numerous piers, then thought necessary for the stability of the bridge, and finally swept it off.

Engineers sometimes make the space between the piers unnaturally wide, to avoid this very defect. A small island in the middle of the stream over which the bridge at Pont de Neuilly was to pass, was removed for symmetry,

and very few piers were erected. The current, which had formerly ran with considerable violence through the narrow space between the shore and the island, had now the space widened. The removal of the island more than made up for the insertion of the piers. In consequence, the stream ran more sluggishly than before, and the equilibrium being disturbed in this direction, the bed of the river began to fill up—becoming shallower and shallower by the formation of a deposit from the sides greater than was carried away by the current. In consequence of inequalities in the bed of the river, one side has become almost silted up by this alluvial deposit, and the arches there closed. The navigation on one side being thus seriously impeded, boats are driven to the other channels. There they meet with a current which has become alarmingly rapid. The silting up of this portion of the bed has left a very small portion passable, and through this the mass of water runs violently, deepening it much, and rendering navigation dangerous, at the same time that it permits the formation of a sort of lagoon at the side, which will gradually deposit more and more of the clays and mud that at present choke up the river.

In the construction of bridges, there are *five* important points to be considered. The choice of their position; the vent or egress to be allowed to the river; the form of the arches; the size of the arches; the breadth of the bridge.

The first of these points is determined, as we have already pointed out, by economical considerations—such as the nearness to a roadway; the convenience and security of a foundation; the convenience of approach; the necessity of leaving a free passage in a navigable river, and the like. The second depends very much upon the determination of the velocity of the stream. This varies, indeed, at different times. It is generally greater in winter, and especially at a time of floods, than in summer, when the water is generally low. It is not the method, however, to take the mean velocity for the year as the datum from which the bridge is to be constructed. It must be built so as to be able to bear the heaviest stress to which it will be subjected—capable of sustaining the shock of a mass of water greater than ordinary coming down with unusual velocity. In fact, this is one of the fundamental points in the construction of a bridge—that it allow a free passage through its arches to the waters of such sudden floods as the river is liable to, and that its arches be sufficiently strong themselves to resist the violence of these attacks. This latter has been already alluded to, and the necessity for a firm foundation consequent upon that pointed out. Another caution evidently suggests itself. It is this—that the top of the intrados (as it is called, namely, the inner curve of the arch) be considerably above the level of the highest water mark which the river makes, even on the exceptional occasion of inundation. If it

be not so, it would clearly result, that in an inundation continuing for any length of time, the bridge would in the first place, by checking the water entirely, cause a flood over of the adjacent country; and in the second place, such an enormous pressure would be brought against it by the constant downward rush of the upper stream that no bridge of any excellence of construction could stand against it long, or help being severely injured by the continuance of such a flood even for the shortest period.

To avoid such evils, necessitates frequently the building of the bridge in places where the banks are pretty high, or the construction of artificial mounds to serve in the same way, with expensive works for the convenience of approach. The old method, which made the bridge rise at the top very much like a semicircle, is entirely given up in modern bridges, as unsuited to the necessities of the great traffic which they must all now be able to support. But this is not the only way of avoiding this inconvenience. It arises as much, indeed, on ordinary occasions, from the greater or less pressure in high floods, due to the form and position of the arch.

Thus take two arches (fig. 2) of the same form,

Fig. 2.

but the one built on such a pier, that at high water—represented in the figure—the water just reaches A, which is called the *springing* of the arch or point from which it commences, while in the other the pier is so low that it reaches the line P T S—the water being at the same height in the two cases, and the arches of the same form—the only difference being in the height of the piers in each case respectively. In the first instance, the water catches on the space P T B D. In the other, only on the space A B E D. There is therefore much less hold given to the descending stream in the one than in the other—that is, it has much less force to push the upper part down the stream, and so overturn it. In a bridge constructed like the first specimen above, a very little rise above the ordinary flood mark would insure all the calamities already described; and the sweep of the water on so large an extent of the building would produce a violent unsettling of its foundations, along with a multitude of eddies, from the large mass of water which, unable to pass the bridge, is thrown back every moment in violent conflict with the descending current. These eddies, producing an uplifting of the soil round the foundation in proportion to their amount, intensify all the effects already described. There is yet another peculiarity in this arrangement which acts even still more effectually. The

river requires, for the maintenance of the velocity above the bridge, that no part of its course be interrupted. If it be at all interrupted, as by the piers it must be, we have seen that an increase of velocity and of depth will take place. If, however, as in the second arch in fig. 2, the piers where it catches the water be regularly built, so that the space interrupted bears a regular proportion to the space left free, the velocity will increase below the bridge, and the bed deepen, until the balance is restored. This will not be materially disturbed by the rising of high water, as the interrupted space will bear the same proportion to the whole open space as before. But, in the other case, this equilibrium or balance will be disturbed immediately when a flood comes. The proportion of the intercepted space becomes forthwith inordinately large, and the velocity, on the principles already established, increases inordinately also, with the violent tendency to deepen the river, and sweep away the foundation of the bridge. The water, therefore, striking upon the bridge with this very great velocity, will be much more dangerous (in the proportion of the square of the velocities) than the same mass could have been at the ordinary rate of passage.

It follows from this reasoning, that it is of very great importance that the springing of an arch should not be below high water mark.

It is necessary, in constructing a bridge, that we should know *accurately* the actual stress to which it will likely be subjected in the event of a flood, and also in ordinary cases. For this purpose, we must measure the velocity of the stream in its natural way, and also in its extraordinary state of floods, near the place where the bridge is to be constructed. This is not so easily done however. Various methods have been proposed for its accomplishment. The simplest, and as it yet seems, the most effectual, is to let a piece of light wood float down the stream, from one fixed point to another. The time when the wood is dropped into the stream, and when it passes the second point, is accurately noted; and, the process having been repeated a number of times, the mean of them is taken finally. We obtain thus, the velocity of the water at the surface. But is this velocity not the same as that below? Evidently not. The water at the bottom goes slower because there is a bed of stone or other matter to retard it. The water in the middle is retarded to keep pace with this slower water, and accelerated to keep pace with that of the top water. It moves at a mean rate. Calculations have been entered into, to show the connection between the surface speed with the average velocity of the whole water of the place—from top to bottom. No very decided results we have arrived at, but one sufficiently satisfactory in practice is stated by M. de Prony

$$u = v \cdot \frac{v + A}{v + B}$$

where u is the mean velocity required, and v the surface velocity, given in metres per second. He finds $A = 2.87187$ and $B = 3.15312$ to give results best reconcilable with both theory and experiment.

A useful consequence of this formula is, that when the velocity v varies between $v = 0$ and $v = 8$ metres per second, that is between 0 and 10 feet per second, which are about its usual limits of variation (0 and 7 miles per hour being nearly equivalent), the mean velocity will vary between $v \times .74$ and $v \times .87$. We may take therefore as a fair rule for ordinary application, though it is only a good approximation—

$$u = v \times .80 = \frac{4}{5} v$$

This gives the mean velocity of the mass of water. But in order to know the shock that will be sustained by a bridge, and the new velocity which will be occasioned at the bridge by the amount of interruption which the piers cause, we require to know further, the amount of water which passes with this velocity. This will clearly be determined by the section of the mass of water at any place, multiplied by the velocity just found for that place. To find this former, we must cross the stream, sounding its depth all over, and marking the depths. We can then gain an approximate knowledge of the surface of the section, which we may suppose represented (fig. 8), by the figure having the level line at

Fig. 8.

the top—the surface of the water; and the curved one at the bottom—the bed of the stream. We take the level one, and measure along perpendicular to it, lines equal to the length obtained by the soundings, at points corresponding to those where they were made; and by joining the ends of these lines, we see that, even with a pretty irregular bottom, we obtain a polygonal figure almost identical with it,—whose area, easily calculable, can be substituted for the accurate vertical section of the stream at the place. We know, therefore, the amount of water passing near the bridge, and the velocity with which it passes—that is, we can calculate how much shock the piers will have regularly to sustain; and also approximate to discovering what velocity the stream will acquire beneath the bridges, when any proposed system of piers interrupts the current.

The *form* of the arch is the next point of importance. There are three forms of special interest. 1. The old semicircular arch. 2. The elliptical arch, usually made, however, as a putting together of several circular arches of different radii; and 3. The segmental arch.

The semicircular arch is used almost exclusively in the more ancient bridge. It is more easily constructed than the other kinds, and it is more solid when it is constructed. But, as its height is half its width, it would require either very high banking, in which case, if a bridge with piers were desirable, it would probably be employed, or else the springing of the arch would be nearer low water than high water mark, and thus the inconveniences already pointed out would result. There is the further objection that it does not offer so agreeable and elegant a "*coup d'œil*."

The other forms, the flat-vaulted arches, as they are called, and the segmental arch, have each their peculiar advantages and disadvantages. They both present less obstacle to the passage of water. Either may be employed where the springing of the arch is above high water mark, without causing such an inconvenient rise from the side to the centre of the bridge, or requiring banks higher than are usually to be found. In the flat-vaulted arches each circular arch is nearly the semicircle of a much smaller form, and the same advantages of solidity and stability securable in the first case are so with them. The lateral pressure of the *voussoirs* (or stones forming the actual arch) is very considerable in the case of the segmental arch, and care has to be taken that the crown does not sink down after the arch is formed in this construction.

Bridges are constructed either of wood, of stone or brick, or of iron. The first is objectionable on account of its rapid decay, especially under constant exposure to water. Some kinds of timber indeed are less liable to decay. Thus oak piles, when entirely submitted to this action, are not liable to rapid decay; but if one part of the same log be in, while another is out of the water, unequal action produces a rapid decay—like the galvanic current, decomposing substances through which it circulates. The ordinary woods moreover change their bulk according as they are wet or dry, and so produce a warping or a bursting action, tending, so far as it goes, to disintegrate the bridge. The cheapness and the convenience of procuring wood is its great recommendation. Besides, when a more secure building, such as a stone bridge, has to be erected, it always requires to have a sort of platform of wood, called *centering*, erected beforehand, and continued as the work proceeds, for the use of the workmen. The material for this, with a little more work, would construct a tolerable wooden bridge. A bridge of iron is objectionable because of the violent expansion and contraction of the material in heat and cold, and from this cause it is not so extensively used as it would otherwise be. Principles of compensation, however, similar in principle to that employed in the compensation balance of a watch, may go far to correct this evil. The other contingency—of the oxidation of iron from exposure to rain and air,

is avoidable by painting and other devices which, however, add a large per centage to the original cost of the bridge. No structures of the ordinary bridge kind, so little obstruct the course of a stream as iron bridges.

Suspension Bridges.—When a chain of iron, or of any metal, is suspended at two points, it takes a certain form depending upon the weight at the various points. The action of gravitating forces draws it downwards—resisting forces, of indefinite capacity, at the points of suspension, keeping it from falling entirely; and cohesive forces transmit this retention from point to point of the whole mass. We can readily understand that these forces will come to balance after bringing the chain to a certain definite position; and that unless the cohesive forces or the retaining power of the points of suspension fail, there will be always a position in which the curve will remain fixed; which position once reached, new forces will be required, again to disturb it. The principles upon which these curves are determined belong to the higher mathematics. If the forces which pull a curve be at right angles to its line, and all equal, an arc of a circle will be formed, as we might have expected from the uniformity of the action and the regularity of the figure. If all the forces applied to be vertical—if, for example, a chain be used, uniform in mass, and permitted to hang freely, a peculiar curve called the *catenary*, or chain curve, results. If the mass be not uniform, there will be deviations from this curve, in the shape of lines that will give greater deflection with the greater weights. If, for example, the forces which act upon each point of the chain are proportional to the lengths of the projections of the small equal parts adjacent to the points, the resulting curve will be a parabola. If the chain be constructed so that these forces are applied to successive points, instead of along the whole chain, a polygon would be formed, having the low points of suspension for vertices, all which points hang along a parabolic curve. We have said that these results will occur, and such curves be formed, unless the cohesive forces of the material of the chain be too weak to stand against the other divellent forces. We can imagine forces of any kind applied to a chain so fixed, and this fixity remaining if the chain be strong enough. This is the idea on which the suspension bridge of the present day is constructed.

Two towers are erected, of such height, that the chain may have its natural swing, and the passage of the river or road not impeded by the bridge hanging over it. A chain of very strong iron is then fixed to the ground at the two ends, and passed up through a passage in the tower, leaving sufficient length to hang in the curve contemplated. Subsidiary chains are suspended to it by various points, and to these is hooked a roadway con-

BRI

structed of planking, over which passengers cross. The chief strain here is upon the towers, which must be capable of resisting the turning tendency of the whole weight in the centre to draw them into the river; and on the chain. The origin of the strain is threefold. First, the weight of the original chain; secondly, that of the subsidiary chains by which the roadway is suspended; and thirdly, that of the roadway and of the passengers. The chains must be strong enough to sustain the tension to which they are severally subjected, otherwise the bridge will fail.

BRI

There is one serious difficulty attaching to the suspension bridge, but it is so serious that it seems to preclude the use of this elegant contrivance except for passengers. The bridge has no stability. Two causes are readily assignable. In the first place, the iron of the chains is liable to great expansion or contraction by heat or cold. And in the second place, the whole structure hanging in the air is liable to oscillate with the wind. No contrivance will probably do away with this latter evil, or indeed with either. Both may, however, be con-

Suspension Bridge across the Danube connecting Dada and Pesth.

siderably mitigated. The best method for doing this is to use as few subsidiary chains as possible; just as in the other construction of bridge it was found necessary to diminish the number of the piers.

An advantage evidently arising from the plan of using very few chains, is this: no two bars of iron are found to expand always alike. Now, if we imagine the vertical and subsidiary chains to expand differently, we shall have this result: the weight of the whole mass pulling the less expanded downwards, and the more expanded relieved of that weight. The whole mass of the bridge may then, and at times does, hang upon one or two chains, and these must be made so strong as to be capable of bearing it. Hence, there is a great waste of material in these chains. If 40 be used, then the whole weight will require to be carried by $\frac{1}{40}$ th of the mass used (roughly), and if only 5 be used, by $\frac{1}{5}$ th of the mass. The latter mass, therefore, may be just eight times less than the former, and must expose, therefore (*ceteris paribus*), a great deal of less surface to the action of the wind. We can go so far, therefore, towards the diminution, but not in this way to the destruction of vibratory effect.

Such are the chief principles, upon which the suspension bridge is constructed.

A very elegant variation of the ordinary suspension bridge goes under the name of Dredge's

suspension bridge. The strain upon different links of the suspending chains will clearly not be quite the same. Thus, in an ordinary chain, the strain will be greatest at one end, and least at the middle. Mr. Dredge calculates, upon mathematical principles, the variations to which the strain is thus liable; and constructs these chains such that the middle links be light proportionally to the strain they have to bear, and the end ones so much the heavier. This secures an economy of material, important in the construction of the suspended chains. He also uses oblique suspending rods instead of vertical ones. The still greater equalization of the strain, and the lessening of it by this particular invention, are capable of mathematical illustration of a not very complex nature. In the bridge, the chains become nearer and nearer the horizontal, the nearer they are to the middle of the bridge. A very beautiful specimen of this construction of bridge is formed across the river Leven, at Balloch, on Loch Lomond, built under the personal superintendence of Mr. Dredge, the inventor.

The figure illustrates the principle. Let $F A$ be a part of the roadway, supported by the chain $A B$; then the force due to $A B$ will pull vertically downwards—being that of gravity

—having, besides, a tendency to make the mass rotate, that is to disturb the fixity of the system by drawing B (suppose the top of the tower) inwards. This is resisted, and there remains a vertical force which we may imagine to pull right down, acting on the rope, through *r*. This vertical force can be decomposed into two—one perpendicular to the line *A e*, and acting on *r*, a supported joint, and another along the line *A B*. This force along the line is evidently smaller than that vertical one of which we spoke, which is the only one acting in the ordinary suspension bridge, and the strain is therefore less. The only limit to the capabilities of this construction is the danger of throwing too much weight on the fulcrum *r*, and of causing a turning effect upon the top, *B*, too considerable.

The suspension bridge, though giving an admirable passage to ships below, was not yet quite capable of fulfilling all the requirements of a modern bridge. Many of them require to admit of the passage over them of very heavily laden trains. Now these two advantages of free roadway, and of sensible stability, could not be combined in the suspension bridge. We annex an engraving of a suspension bridge.

The *tubular bridge* was devised to combine these advantages. We shall avoid, however, entering into its principles at length.

The chief point upon which the construction

of tubular bridges rests, is the capability of wrought iron to resist a tension much greater than cast iron can. The old iron arch bridges were almost all built of cast iron. Cast iron bears a transverse strain better, and the wrought iron a strain lengthwise; and at the time of construction the bridge might be made, so, that when without passengers, the two should work completely together—the transverse strain borne by the cast iron, and the lengthwise one by the malleable iron. Unfortunately, this is not the purpose for which bridges are constructed, and it is easy to conceive loads so placed on the line, that each strain would fall to the mass least fitted to sustain it. A melancholy instance of this occurred on the bridge over the Dea, on the line of the Chester and Holyhead Railway. It broke down completely on the 24th May, 1847, occasioning serious loss of life.

The tube through which the roadway runs in the tubular bridge sustains all the weight in its various parts. It was a question of the utmost importance to determine, where the great stress on the tube would be, and what would be the form best calculated for strength. Both of these matters required experimental determination, and a series of experiments as elaborate as any on record were entered into, under the direction of Mr. Robert Stephenson, by Messrs. Fairbairn and Hodgkinson, the results of which will be found de-

Britannia Tubular Bridge across the Menai Straits.

tailed at considerable length in the recent supplement to Brunell's *Theory of Bridges*. It came out in the course of these investigations, that the Circular and Elliptical tubes were not nearly so well fitted to sustain a weight passing through them as the much more simply constructed rectangular one; and the remarkable fact was elicited, that the iron ought to be made thicker at the top of the tube than at the bottom, because there was

the greatest strain. This is a consequence of the fact already noticed, that wrought iron is much less capable of sustaining a transverse load than cast iron is, although on the other hand it is far more capable of bearing a lengthwise strain.

The magnificent series of inventions by which all the details of these bridges have been perfected, has, perhaps, no parallel in modern engineering. Every point connected with their con-

struction, the riveting of the plates, the construction of the tube, the elevation of it without centering or scaffolding of any kind, has given scope for an ingenuity, equally remarkable for its energy and persevering application. This last idea—that of erecting a bridge without scaffolding—gave Mr. Stephenson the first notion of a tubular bridge. It had been proposed to raise a bridge over the Menai Straits, to facilitate intercourse between Dublin and London. The Admiralty, however, required that, in the construction of this bridge, there should be a clear height of 100 feet left across the whole channel, even during the time of construction. This—to any other man—would have been a simple veto on the construction of a bridge of 1,500 feet long; but it conducted Mr. Stephenson to the construction of the Britannia tubular bridge. See **SKEW-ARCH**.

Brittleness. A property of bodies, which although solid, yet are so weakly bound together, that a very small mechanical force suffices to separate their particles. They can be easily reduced to powder. The cohesive force between their perceptible particles almost vanishes, but they differ from liquids in possessing a considerable cohesive force, acting between the particles which are so small as almost to be imperceptible.

Burning Glass. We shall see in the articles **CATOPTRICS** and **DIOPTRICS**, that rays of light diverging from one point, and falling upon mirrors of peculiar shape, may be thrown back from them, so as all to intersect in one point, and that if incident upon a lens of peculiar shape, they may pass through it, emerging in such a direction as also to concentrate about a particular point.

Thus, for the first case, we shall see that small concave spherical mirrors will throw back rays coming from a point tolerably distant, so as to intersect very nearly in one focus; and if the rays be parallel, as some rays are, or the point from which they come very distinct, which is the cause of this parallelism, we may have with a concave mirror which has a very small central angle, this concentration of rays as accurately as we may choose. The rays incident upon a spherical mirror convex to these lines of incidence, do not pass, when reflected, through the point from which they diverge at all. Their focus is behind the mirror.

We shall see, also, that a paraboloid mirror, turned concave to the line of incidence of the rays will reflect parallel rays, as from the sun, or moon, or a star, accurately to one point, and that an ellipsoidal mirror will reflect rays diverging from the one focus, accurately on to the other. With a mirror of the hyperboloid form the same result would be obtained as with a convex spherical mirror; the rays, when reflected, would appear to diverge from a new point, but this being behind the mirror, they would not actually pass through it.

Now, the sun's rays possess a heating as well as a luminous power; and although different rays do possess this power in different degrees, yet, as the different nature of rays causes no deviation in any of them from uniform laws of geometrical reflection, and as none of the component parts of white light are separated in ordinary reflection, we may consider each ray of ordinary light as simply possessed of heating power. Let a number of heating rays, therefore, diverging from any source of heat, fall upon a mirror from which they are accurately reflected, so as all to cross one another at a given point. It is plain that at that point there will be a very great concentration of heat, and that bodies placed at it may be subjected to a very high temperature. This is the principle upon which burning mirrors are constructed. The readiest source of heat is the sun, and the mirrors hitherto employed have been made principally so as to concentrate its rays. In the expressions by which the radius of the mirror and the distance of the luminous point from it are connected with the distance from it of the focus of reflection, we have simply to make the distance of the luminous point become infinite, as in comparison with all ordinary terrestrial distances it may in this case be fairly considered, in order to apply the ordinary formulæ to the action of sun rays.

The substance of the mirrors should not be transparent. But, for the second case, that of burning lenses, the transparency of the glasses is the property on which their power depends.

We find (see **DIOPTRICS** and **LENS**) glasses of this character, that they gather light coming from a point, and falling scattered on their surfaces into another point behind the lens. Some, indeed, like the convex mirror already noticed, only scatter the rays less, but still allow them, after passage, to go on diverging, as if they came from a point through which they do not, in reality, pass at all. These lenses are as useless for our purposes as the similar mirrors were, but wherever we have lenses which concentrate luminous rays after passage, towards a point through which they really pass, we can use them for burning glasses. Frequently any lens which could conveniently be made, more frequently any which we may actually have in possession, will not throw the rays exactly toward the point where we desire to concentrate them. And in that case we may combine two or more, so as to prevent the convergence of the rays to a point too near, by a slight dispersive power, or to make the concentration still more intense than after passage through the first lens. Here, however, we are met by the fact of the dispersion of ordinary light by refraction through lenses. There is one focus for the violet, another for the red, another for the blue rays of the spectrum. If, therefore, the heating power of the solar ray be uniformly distributed among the various homogeneous rays, we shall require to use for burning lenses the

CAL

same arrangements which we have already seen to be necessary to prevent chromatic dispersion. It has been fortunately, however, found that the more refrangible rays, those towards the violet end of the spectrum, possess very little heating power. The experiments of Sir W. Herschell, in 1800, proved that the calorific effect at the various points of the prismatic spectrum was greatest for the extreme red rays, and extended even considerably beyond it, and beyond the spectrum. Hence we may take the sort of mean index of refraction for the heating rays to be very nearly the index of refraction for these extreme red rays. By convenient lenses accordingly, we may concentrate these rays at the foci of our lenses, and obtain a considerable heating effect also upon objects very near the focus of the lens, upon either side of it. Arrangements similar to the achromatic arrangements, by which the dispersion of colours is prevented, would undoubtedly, however, very largely increase the heating effect.

The principle upon which burning glasses are constructed is, therefore, simply this,—that the heating rays, either from the sun and other heavenly bodies, as is most usual, or from other sources of heat, be concentrated as nearly as possible to a point. This is effected in burning mirrors without regard to the dispersion of heterogeneous rays; and, in the case of burning lenses, we may either employ arrangements akin to those in achromatism, or with simple lenses may construct them as if intended to collect the extreme red rays. The burning lens is convex, as the burning mirror is concave.

The use of burning glasses is certainly very ancient. Aristophanes mentions them in "the clouds." The celebrated exploit of Archimedes, who set fire to the Roman fleet at Syracuse, by means of a burning mirror, rests upon a mass of historic testimony not easily set aside. The use of lenses is certainly not much more modern. Pliny mentions balls or globes of glass or crystal, which, when exposed to the sun, are capable of transmitting sufficient heat to set

CAL

cloth on fire, and Clemens Alexandrinus and Lactantius suggest the employment of globes of glass filled with water.

In order to give some idea of the power of these instruments, we shall transcribe an account of one made by Mr. Parker. His lens is made of flint glass, and when exposed, has a clear surface of 32 inches diameter. Its thickness in the centre is $8\frac{1}{4}$ inches, and its focal length 6 feet 8 inches.

He used, along with this, another lens having a clear surface whose diameter is 13 inches, whose thickness in the centre is $1\frac{1}{2}$ inches, and whose focal length is 29 inches. This lens, when arranged along with the other, still further concentrates the converging rays which have already passed through it. It was placed by him so that the focal length of the two was 5 feet 3 inches. A number of experiments gives the following series of results:—

Substances fused, with their weight, and the time occupied in fusion,—

	Time in Seconds.	Weight in Grains.

C

Calculus, the **INFINITESIMAL**; or the *Transcendental Analysis*:—the names usually given to that great branch of the Mathematical Sciences, which, since the time of Leibnitz, has commanded, by one general method, the most arduous problems in geometry, mechanics, and physics. Perhaps the simplest definition that can be given of this potent Algorithm is the following:—*In ordinary Algebra, the values of unknown quantities, and their relations with each other, are detected by aid of equations established BETWEEN THESE QUANTITIES DIRECTLY;—it is the fertile artifice of the Calculus, on the other hand, to arrive at such systems of direct equations by means of other equations primarily established not between*

the quantities themselves, BUT BETWEEN CERTAIN DERIVATIVES FROM THEM, OR ELEMENTS OF THEM. It is found much more easy in practice to determine the equation between such elements and derivatives, than between the primary quantities; when this is accomplished, the problem may be said to be *laid* analytically; and the subsequent process—that, viz., by which equations between the primaries, are deduced from the relations of the derivatives—is a simple process and difficulty of pure analysis. The fundamental requisition of the Calculus, was evidently this—to establish rationally, the notion of these *derivatives* or *elements*. Three schemes have been proposed, amounting to the same thing in practice,

but differing in the strictness of their logic, as well as in the facility of their application. If one would find the true logic of the new Calculus, recourse must still be had to that memorable section of the *Principia*, in which Newton exposes the theory, and demonstrates the chief theorems, in the Method of the *Ultimate Values* or *Limits* of the Ratios of variable quantities. This conception or principle of *Limits*, is now universally adopted in establishing the foundations of the Transcendental Analysis by all rigorous logicians; nor is it easy to see that any other course is open. Dissatisfied with the conception or *Limits*, as not a purely analytical one, and also dissatisfied for similar reasons with the original method of Leibnitz—the illustrious Lagrange offered a new mode of contemplating the origin of these *derivatives*. Presuming to have demonstrated that any function of $x = \phi \cdot x$, could, after x had received an increment h , be developed in a series as below:—

$\phi(x + h) = \phi x + A_1 h + A_2 h^2 + A_3 h^3 + \&c.$, in which $A_1, A_2, A_3, \&c.$, should contain the variable x only—he required that these coefficients, $A_1, A_2, A_3, \&c.$, should be accounted the successive, or the *first, second, third, &c.*, derivatives of $\phi \cdot x$: and so averred that the nature of these derivatives could be presented as flowing out of a purely algebraical relation or law,—the gap thus being filled up that had appeared to separate in *logic*, the Algebraical from the Transcendental Analysis. Notwithstanding the fair appearance of the *Theorie des Fonctions*, it cannot be said that Lagrange has succeeded. No equation, on one side of which is an infinite series, can be termed independent of the idea of *limits*; simply because it means that the finite side is the limit of the infinite side; nor were the several steps by which Lagrange reached his demonstration of *Taylor's theorem*, unmixed with the same class of considerations. And what is still more formidable, is the fact, that the application of the Calculus under its new form, turns out for the most part so cumbrous and inconvenient, that Lagrange himself abandoned it in his *Mécanique Analytique*, for the much easier processes of Leibnitz. This latter extraordinary genius—to whom the first systematic statement of the principle of the Transcendental Analysis is incontestably owing—presented it originally under its *third*, and in use, still its favourite form, that of *Infinitesimals*. Not wholly unlike the manner of Cavalieri in his once famous method of *Indivisibles*, Leibnitz considered all quantities or magnitudes made up of *infinitely small elements* or *infinitesimals*, named *differentials*; and he showed that in the great majority of cases, the relations of the quantities concerned in a problem, might be much more easily expressed, by equations between these elements, than between the primary quantities. Sometimes it turned out difficult to establish even these equations; but in that case, *the end might be gained* by decomposing the

differentials themselves into other infinitely small elements, and seeking relations among such *second differentials*: or still further, differentials of the third order in descent might be resorted to; and so on in the same manner. There cannot be a doubt that Leibnitz's conception is of all others the most facile in practice; so much so, that it may be said to be the only conception in the mind of any one extensively employing the Calculus; but at first it appeared objectionable in principle. The idea of Infinitesimals itself, cannot be termed a just or pure analytical idea; and in the working of it out, according to the methods of its inventor, one is called upon at every step to reject infinitesimals as being *incomparable* with finite quantities, and the higher orders of infinitesimals as being incomparable with lower ones,—a process bearing much too close a resemblance to a mere process of approximation, to be received without scruple as the instrument of exact inquiry. Geometers did not soon succeed in discovering why, out of methods wearing on their front the garb of mere approximative methods, the exactest results were, through some necessity, evolved. D'Alembert, Euler, and others, sought the key of the puzzle in vain. At last Carnot detected it. The methods of Infinitesimals are correct, through effect of an *exact compensation of errors*: if the equations originally formed are in error, or, as Carnot termed them, *imperfect*, through neglect of quantities infinitely small in comparison with the quantities entering into these equations,—*a process occurs of precisely the reverse nature when these auxiliary equations are finally raised to equations between finite quantities*; which last are therefore and necessarily *perfect* equations. The logic of the processes of Leibnitz, vindicated in this way, the sole objection that remains to the method of this geometer, has reference, as we have already said, to its being founded on a conception like that of infinitesimals.—Such in general the nature of the ideas on which the Transcendental Analysis is founded; let us now enumerate and briefly delineate its main divisions. It is sufficiently evident that a Calculus which proposes to discuss and determine the relation of quantities from relations established between other quantities derived from them, must consist essentially of two principal parts. *First*, it must explain the rules by which, the primitive quantities being known, the analyst may determine their *derivatives* (*fluxions, infinitesimals, differentials*); and *secondly*, it must explain that inverse set of rules or methods by which the primary quantities may be deduced from, or detected by aid of, these derivatives. We shall offer a few remarks on each of these great divisions.

(1.) *The Differential Calculus*. It is the object of the Differential Calculus to lay down, how we obtain the derivatives of each of those few simple functions or modifications of quantity which are alone recognized in analysis; and this, whether

these functions are presented singly or in any form of combination. The functions are—the *sum* of variables, their *difference*, their *product*, *quotient*, *power* or *root*; *exponentials*, *logarithms*; and *direct* and *inverse circular* functions. Now, the Differential Calculus, as thus defined, may be termed *complete*. We can *differentiate* at will any of these known functions, or any combination of them whatever. It is of no consequence whether the function to be differentiated (or made to yield its *derivatives*) be explicit or implicit: the known methods of derivation apply to all cases; and with equal ease, any function may be differentiated a second, third, or any number of times, or pursued to any order of its derivatives. This Calculus in itself is susceptible of many important and interesting applications, such as to problems of *maxima* and *minima*; but these we cannot at present notice.

(2.) *The Integral Calculus*.—The *Inverse* portion of the Transcendental Analysis is very far from being as perfect as the former. Its methods, instead of being general, are little better than happy artifices whose origin is mostly due to the occurrence of difficulties in the treatment of geometrical, mechanical, and physical problems; nor are there many analysts who would be inclined to question the opinion of Laplace, that *integration* is one of those difficulties whose general solution we cannot hope for. The remarks that can be offered here are so few, that we shall wholly leave out of view the question of the integration of implicit functions, or of *differential equations*,—an immense subject, of which, in comparison with its extent, we can scarcely be said to know anything. Explicit differential expressions are those that take on the following form:—

$$\phi x. dx.$$

—simple enough as so expressed; but the integral even of these cannot be found unless with regard to a few of the more elementary forms of $\phi. x$. If $\phi. x$ be either an *exponential*, a *logarithmic*, or a *circular* function, the integral of the foregoing expression cannot be directly found unless in a very few and simple cases; to treat which even, generally requires great ingenuity. One of the leading artifices applied in this case, is the *Integration by Parts* of John Bernoulli; by whose means a difficult expression may often be reduced to another more easily reduced. If, on the other hand, $\phi. x$ includes only the common algebraic functions, we still cannot treat the case generally, unless $\phi. x$ be *wholly rational*. If it is irrational, it cannot be treated at all unless in the few cases in which, by substitution, it can be rendered rational. It may be said, therefore, that the Integration of rational functions is really the only portion of the great inverse problem of Analysis over which we have yet entire command. Want of space constrains us only to refer by name to methods of Integration by *approximation*, or to that curious Transcendental Arithmetic, known as *Definite Integrals*. We cannot omit,

however, an expression of regret that we are not enabled to explain, in reference to Differential Equations, the most ingenious and admirable method indicated by the name of *Singular Solutions*. The student must apply for details to some of the excellent text-books now common in this country.

(8.) *Calculus of Variations, Calculus of Finite Differences, Calculus of Functions*.—For brief notices of these important off-shoots from the original Transcendental Analysis, we refer to VARIATIONS, DIFFERENCES, FUNCTIONS.

Calendar. A distribution of time, accommodated to the uses of ordinary life. In seeking for some base upon which to rest such a division, the first that suggests itself, as being the widest, for which we have an evident physical ground, is the division into revolutions of the sun round the earth, or of the earth round the sun, i. e., from equinox to equinox. Upon this depends the cycle of the seasons. Another unit, however, independent of this, seems to have equal claims on us; viz., what is called the civil day, or the interval of time from one passage of the meridian by the sun, until his next passage of it. If, then, we should adopt *either* of these as the unit of time, and the standard of our measurement, we should have good physical grounds upon which to proceed; but would require a peculiar nomenclature for parts of the unit not *aliquot* (as in the case of the day and the year); or for multiples of the unit by fractional or mixed numbers, for the odd hours (5 hours, 48 minutes, 50 seconds), of the day. In fact, the day and the year are each of them so important, that we are forced to give up all hope of the adoption of one standard, and a uniform system, and consent to the admission of two independent units. We could, indeed, speak of the year as $\frac{8155698}{8640}$ of a day, or of a

day as $\frac{8640}{8155698}$ of a year, and there would be some advantages in so doing; but these would be far more than counteracted. We are forced, therefore, to employ the two units conjointly. Attempts have been made even to introduce another independent unit. The period of the moon's revolution, next to that of the earth's annual and diurnal period, is undoubtedly the most prominent, and it has accordingly been chosen. This has not, however, been generally adopted. The system almost universally used rests upon the smaller of these natural units—the civil day. We endeavour to adapt the year, by various contrivances, (see *BISSEXTILE*) to the day; so that we may not have the commencement of our civil years, far from the actual commencement of the true year; while we are enabled, for the sake of convenience, to consider the year as made up of a number of *whole* days. We are desirous of this latter result, for the facilitating of calculations, which would be very tedious if we

had to consider in what part of the year any moment of any particular day might chance to be; and of the former, that so we may be enabled to compile rules of meteorology for our observations,—rules that may be applied without changing our time from the diurnal standard of measurement to the solar, or *vice versa*. A calendar approaches perfection, the more closely it fulfils those two conditions.

A sort of Epicycle system has been introduced to fit on to this kind of calendar, which is intended to secure the same practical coincidence between the commencement of the month and of a lunation, or revolution of the moon; while it permits us to count each lunation as made up of a number of whole days. Attempts to reconcile practically the commencements of the year and the lunation, have also been made. The Athenians thus tried to reconcile the commencement of a month, composed of a number of whole days, and a lunation, and made the months to consist of 29 and 30 days respectively. This method might do extremely well, but for the inconvenience that 12 of these months would only give 354 instead of 365 days, and that the remaining 11 days would confuse the arrangement. In fact, practically it has been found in most nations that the unit of a lunation is by no means so important as that of a day or of a year—that the physical circumstances which complete their cycle along with it, are comparatively few; and that as the introduction of it into the calendar complicates further a system which is, for the common people, already complicated enough, it is unnecessary and would be troublesome. Hence, as 12 is nearer than any other whole number of lunations to the space occupied by a year, we divide the year into 12 months, appointing the number of days in each month as approximately, perhaps, as the case will admit of, to be 31 and 30. What is called the *luni-solar* calendar, has, in fact, been found quite useless. The Grecian and Macedonian calendars were based upon it, and the calendars of the Eastern nations, the Hindoos, Chinese, and Japanese, still are. It is not used in Europe at all, except by the Jews.

What is called the purely lunar calendar—in which the return of the moon is taken as the chief unit—but which rather is the one resting on the two units of the day and the lunation, has little physical foundation. It is, in consequence, not very extensively used. Here we have to consider the lunation, as consisting of so many whole days, and we have to arrange the number of days in the month so that 12 of them will come to make up a period of 354 days, 8 hours (the period of 12 lunations). If we make each month to consist only of whole days, the smallest cycle which we can employ will be three times that, or 1063 days, in which 36 lunations will be accomplished. The professors of the Mohammedan religion use this lunar calendar: but the confusion which it introduces into the

seasons, and the practical restraint it puts upon agriculture, by making their various periods of time not at all correspond to the recurrences of the principal influences of meteorology, have prevented its being introduced anywhere else.

Some of the more ancient calendars made very slight attempts at any reconciliation of the two standards of the day and the year. These could only be, and were only tolerated, in the infancy of astronomy.

We shall just mention rapidly in conclusion, the methods by which the day and the year have been sought to be kept as bases of one system, by successive nations.

The Egyptian method is perhaps the most ancient, and one of the most interesting. In theory it is almost identical with the Julian method, yet how different in its practical results! It divides the year into 12 months of 30 days each, with 5 additional intercalary days (*i.e.* belonging to no particular months, but makeweights, as it were). This year of 365 days, however, is in error $\frac{1}{4}$ day each year, and, therefore, 365 days ($1460 \times \frac{1}{4}$ days) in 1460 years (*magnus annus*). Hence at this period we should come back to our true starting place, and the commencements of our civil and natural years would agree. It is needless to remark on the inadequacy of this method. It would only be endurable for $\frac{1}{4}$ part of the time, during each *magnus annus*, within which the error would not be more than a month either way; but for the other 1217 years we should have the seasons all altered from their standard positions by at least more than a month.

The Persian method made nearer approach to a good calendar. They had the same system of 12 months of 30 days each, with 5 additional intercalated days; but they added a thirteenth month (30 days) at the end of each 120th year. This secured a counterpoise for the errors of a quarter of a day per year, accumulated during that period. During 60 years of each 120, however, the year was still more than a fortnight out of place, and though its restoration to a true state was indeed provided for, the fact of that error was not removed, and the same provision which at first brought back the true year brought back the error afterwards. The Julian method, and the Gregorian, with the various improvements which may be applied to that, when necessary, are detailed in the article BISSEXTILE. The Julian provided for a restoration, every four years, of the agreement, and if the true year had been $365\frac{1}{4}$ days, would have been perfect. The Egyptian and Persian methods failed also in considering this as the true year, although the close approach to the truth is much more remarkable in this case than the slight deviation from it. The methods by which the day and the lunation are brought to agree, are detailed in the article CYCLE.

Calibre :—the diameter of the chamber of fire-arms. The word is mostly used in regard to mortars, howitzers, and swivels. The dimen-

CAL

sions of cannon are usually indicated by the weight of the bullet.

Calippic Period. See CYCLE.

Calliope. One of the asteroids. For elements, &c., see ASTEROIDS.

Caloric:—a technical term once extensively used in physical science. It was meant to stand in that opposition to, and connection with, *Heat*, that *Cause* does to *Effect*. By *Caloric*, physicists meant the hidden cause of the sensation and phenomena of *Heat*. The term is now dispensed with. The entire theoretical part of the subject will be treated in this Dictionary, under **HEAT**.

Calorimeter. An instrument intended to measure the amount of heat contained in bodies. Various calorimeters are in use. The one perhaps most simply explained is constructed as follows: Take a cylinder and put in it a known quantity of the hot substance, the amount of heat given off by which it is to be examined. Surround it with another cylinder filled with unmelted ice, which, in order to prevent communication of heat to it from the air, is enclosed in a third cylinder also filled with ice. A pipe from the bottom of the second cylinder conducts the water that flows off. It does not communicate with the water melted from the ice in the third cylinder, although its mouth be placed quite at the bottom of the second, for the ice remaining in the third being lighter than the water in it, this water is kept at the bottom, and is not permitted it to reach the mouth of the tube. The body inside will then be reduced to 32° , and the water that comes out is measured. Now it is known that it takes 141° Fahr. to convert ice into water. If we know then the amount of ice melted, 141 times the number of lbs. in it is the number of thermal units Fahrenheit given off by the body experimented upon. If, further, the number of lbs. in the body be known, we can easily calculate the number of thermal units given off by each lb. of the substance, in falling from the temperature at which it was introduced into the cylinder to 32° Fahr. A lb. of water would fall in that case by as many thermal units as the degrees in temperature, less by 32° —and dividing that result by this, the *specific heat* of the body is obtained. To ascertain this is the ultimate aim of the calorimeter.

This method, however, which Lavoisier and Laplace employed, is found, though theoretically, very excellent, to give practical results far from trustworthy. Another consists in mixing a certain weight of the body, to be examined, with a definite weight of water, and observing the temperature of the mixture. Thus; suppose a pound of metal filings, at 80° Fahr., be set to float in a lb. of water at 100° Fahr., and the resulting mixture be found at the temperature 99° Fahr., this would prove that the loss of one degree of *temperature* from water compensates for a gain of 19° in *temperature* of the mixture. The amounts of heat lost and gained must be, how-

CAL

ever, the same, and hence it only takes 1-19th part of the heat to raise a lb. of the metal through one degree that it does to raise a lb. of water. The specific heat then is 1-19th. This is the principle on which the process founds. There is also the method of cooling, which gives the most satisfactory calorimetric results of all. The substances are placed within cylindrical vessels, heated to the same temperatures, and allowed to cool down. The cylinder, with a constant form and quality of substance, radiates off the same amount of heat for the same *given temperatures*, so that the time of cooling of the respective bodies through, say 1° of *temperature* will indicate the comparative amounts of heat which each body possessed. If thus, the one takes five minutes and the other two-and-a-half, there is given off twice as much heat by the first body as by the second, with the same lowering of temperature. It takes, therefore, *vice versa*, twice as much heat to raise the first through one degree of temperature as the second. The specific heat is thus found. The reader will readily see that the two bodies will not be *quite* at the same temperatures, at any instant after the first, and the process above, founding on a law that assumes this, will require certain modifications.

Calotype. This name, signifying beautiful picture, is the term chosen by Mr. Fox Talbot to designate the exquisite process of his invention, by which the images of the camera obscura are fixed on paper, from which afterwards other photographic copies are taken, and pictures produced equal in accuracy and effect to those of the celebrated daguerreotype, and, indeed, in some respects greatly superior. The distinguishing peculiarity of the calotype consists in the use of the organic substance, gallic acid, to heighten the sensitiveness of the salts of silver. The general fact that organic substances, when mixed with solutions of nitrate of silver, tend to aid its decomposition by light, has been long known. For example, we may safely expose without change to the rays of the sun a bottle of nitrate of silver dissolved in distilled water. But if the water has been river water, or contains even the smallest quantity of animal or vegetable matter, an immediate decomposition commences, and in a short time a black precipitate at the bottom of the vessel shows us that we have neglected to cover the bottle with an opaque wrapper. Mr. Talbot has the merit of having taken full advantage of this property, and thus rendered an inestimable service to photographic art.

Since the first publication of the process, experience has shown that in some of its details it may be somewhat improved. It will not be necessary here minutely to specify many of these, but rather, to prevent confusion, to confine ourselves to two, which seem to be the best in their effects and the most certain in their results. The first to be mentioned, viz., that in which the

gallo-nitrate of silver is used, is the most sensitive, and will, therefore, be used for portraits and other purposes where speed is required. The other, wherein the acid nitrate of silver in part takes the place of the gallic acid compound, is less delicate, and, perhaps, more certain, requiring a longer time of exposure in the camera, and is therefore only suited for landscape views and the copying of still life.

The paper selected should be free from spots when seen by transmitted light; Carson's answers well. Being cut to the required size, it is to be subjected to the first process, called iodizing. This is done, either by the double process—that is, by the application first of the nitrate of silver, and subsequently by the iodide of potassium—or by the simple process of applying the iodide of silver at once. The latter is now considered the preferable mode; iodized papers are also sold in the shops ready for use. The double process of iodizing is as follows:—The paper being fixed by silver pins to a board slightly larger than itself, is held nearly vertical, and brushed evenly and thoroughly from above downwards, with a solution of nitrate of silver, twenty grains to the ounce of distilled water. The brush must be large and soft, and no running or superfluous liquid must be left on the paper. It is now allowed to hang and dry. In some respects, a better process is to employ a larger quantity of the solution, and to float the paper on it in a flat dish, slightly turning up the opposite edges previously, and taking care that the back be kept dry. Supposing now that the silver coating has been, by either of those processes, properly applied, by the light of a taper or candle the paper is now to be placed with the prepared side on the surface of a solution of iodide of potassium, twenty grains to the ounce of water, with the addition of five grains of common salt, this being poured into a flat dish of the proper size. Care must be taken to keep the upper side dry, and that the lower be thoroughly wetted by drawing it back and forward. It may be allowed to remain on the solution for about three quarters of a minute, or a whole minute, but not longer, as the iodide of silver would be redissolved. Having dripped off the superfluous adherent solution, place the paper on its back to allow time for a complete penetration, and the thorough change of the nitrate to the iodide of silver, so that no black stains afterwards may result from neglect. It is now to be floated with the prepared side downward, on a vessel of clean water, which easily moistens the whole surface, as it has been placed on it when only about half dry. It is allowed to remain for ten minutes, in order that the size which has been formed on the paper, and the remaining iodide of potassium may be washed away. It is now to be hung up to dry. In this state the paper will keep, if enclosed in a book, and light excluded, till the period when it is to be used in the camera. The

next part of the process, which is called *exciting* the paper, is only to be carried out shortly before it is to be exposed—indeed the shorter the better, and in general more than twenty-four hours should not elapse. The room must be thoroughly darkened, and no other light used than that of a candle at the distance of a yard. The exciting liquid called the gallo-nitrate of silver is prepared by mixing equal quantities of the two following solutions, viz., a saturated solution of crystallized gallic acid in distilled water (excess of crystals being always kept in the bottle, and allowed to subside for ten minutes before pouring out), and a solution of 50 grains of nitrate of silver to each ounce of distilled water, to which last has been added $\frac{1}{4}$ th of its bulk of glacial acetic acid. Solutions of half these strengths are more certain in their results, though less rapid in their action. This mixture is to be made in such a quantity only as is indispensably necessary for properly moistening the surface of the paper, and is to be used immediately, as it begins in a few minutes to undergo spontaneous decomposition. For applying it to the iodized surface of the paper, either of the following modes may be adopted. A piece of smooth and flat plate glass is to be converted into a shallow trough by having a small slip of paper pasted round it, to prevent any of the liquid running off, if it should happen to come to the edges. This plate being rendered level, the requisite quantity of the gallo-nitrate is to be spread over it with a glass rod, and the prepared paper gently pressed into contact with it, all over, care being taken still to keep the upper side dry. The paper may also be pinned down by silver pins to a piece of wood, and a smooth glass rod laid on it. In front of the rod, and in contact with its whole length, the gallo-nitrate is poured, and is then spread over the paper by gently and steadily moving the rod forward over the surface. As soon as the surface has been wetted by either process, the paper must be immediately removed into a vessel of water, and washed by moving gently, changing the water several times. It must be allowed to drain for a little, and then placed in the camera, or if that is not convenient, it is pinned up to dry, and, while still somewhat damp, put into the slide or the portfolio with care, remembering the tender nature of the sensitive surface.

The time of exposure for this very sensitive paper will, of course, vary with the strength of the light, but in general from thirty seconds to four or five minutes will suffice. On being removed from the camera slide, which must be done only in the feeble light of a candle or a small piece of yellow glass inserted in a window-shutter, no picture will be visible, the process called *development* being necessary. This is effected by the reapplication of the same gallo-nitrate solution, and in the same manner as before. As soon as this is applied the picture is to be held against a

CAL

jet of steam issuing from some such apparatus as a common tea kettle. The development must be watched, the high lights appearing first as dark spots, and other parts coming out successively till even the smaller details begin to appear, when it is to be immediately washed by dipping in water.

The picture is now to be *fixed*, or rendered insensible to further change, by steeping in warmish water, renewing it several times—and is then to be pressed between folds of bibulous paper. It is now allowed to soak for about a day in a solution of hyposulphate of soda of the strength of half an ounce to twenty ounces of water. Nothing further is necessary than to thoroughly wash this last solution out of the paper, by allowing it to soak in a large quantity of water for several days, frequently changing the water, until every trace of a sweetish taste is gone, in order to insure that none of it be left. If this be not attended to, the effect will be a slow decomposition of the dark parts of the picture, by which, in the course of time, it will be injured, if not altogether obliterated.

The picture so obtained is what is called a *negative* picture, that is, the lights and darks are reversed, so that another process becomes necessary for again reversing this, and producing the same appearances as in nature. In this case the camera is unnecessary. The negative is placed with its prepared side on the sensitive surface of another sheet of paper; a piece of glass is pressed on both to insure close contact; sunlight is allowed to penetrate the negative and to darken the parts opposite the lights on the second or sensitive surface, while the parts opposite the opaque portions of the negative are protected; and we thus get a reversed copy, with the lights as in nature. This is called printing.

Various modes of *preparing the sensitive paper for printing* have been adopted, in some of which the albumen of eggs is used to give additional sharpness to the impression. The following process answers well. Dissolve fifty grains of nitrate of silver in an ounce of distilled water, and, drop by drop, add strong liquid ammonia, till the liquid, which at first becomes turbid, again clears, taking care not to add more than is sufficient. Prepare the paper by dipping it in a solution of common salt in water, of the strength of two grains to the ounce; press it in blotting paper, and having allowed it to dry, the fore-mentioned solution of silver is to be brushed over it in the manner formerly mentioned in the preparation of the calotype paper, or it may be spread on the glass slab, which is preferable. Allow it to dry, and the paper is fit for use. It is to be placed under the negative, as formerly mentioned, and exposed to light. The progress of the printing must occasionally be watched, by removing the glass and papers into a darkened room, and cautiously lifting the edge of the negative, which is prevented from shifting its place

CAM

by the finger or a little gum. The process is only to be arrested after the exposure appears to have been somewhat excessive by the darkening, slightly, even of the most protected parts, or what are the highest lights. The subsequent process, of fixing, restores them, having a tendency to lighten the whole picture. It is now to be steeped for a short time in warm water, and soaked afterwards in the same strength of a solution of hyposulphate of soda, as used in the calotype negative, and well washed in a succession of waters, so as to remove the last trace of hyposulphate.

The modified process of the calotype, in which aceto-nitrate of silver is used, with only a small quantity of gallic acid—alluded to at the beginning of this article, may now be described. A solution called the aceto-nitrate of silver is to be prepared as follows:—Nitrate of silver, thirty grains; acetic acid (glacial), one drachm; water, one ounce, can be mixed together. The iodized paper, as in the ordinary calotype, is, by either of the processes formerly described, to be evenly wetted with the following mixture, prepared at the moment only in barely sufficient quantity:—into a small glass measure or conical wine glass, in which has been inserted a filter of bibulous paper, about the size of a half-crown piece, drop, so as to filter it, four drops of the aceto-nitrate solution, then removing the filter, add two drachms of distilled water, and then drop in four drops of the saturated solution of gallic acid. This having been spread on the iodized paper, is to be allowed to remain on for fifty or sixty seconds, when it is to be blotted off with a single sheet of bibulous paper. Allow it to remain until half dry, and it is ready for the camera. The time of exposure in the camera may be from four minutes to half-an-hour, according to the nature of the subject and the strength of the light. It is now to be developed, which ought to be done within a few hours after its excitement. This must be carried on, as well as the preparation, in a darkened room, and with no other light than that of a candle. For the development, first, as much of the gallic acid solution must be poured on as when spread with the glass rod, to cover the surface; then pour on about a similar quantity of the aceto-nitrate of silver, and having also spread it, allow the whole to rest during four or five minutes, after which, pour on and spread a little more gallic acid, repeating the same operations till the development is completed, taking care in each of the processes to wet the paper quite to the edge, to prevent warping. It is now to be washed in three or four waters, and afterwards fixed as in the process already described.

Camera Lucida. This instrument is more recent in construction than the Camera Obscura. There are two different instruments to which the name is applied. The first is that of Dr. Hook. It is described as a contrivance for making the

CAM

image of anything appear on a wall in a light room, either by day or by night. He requires a large hole, about a foot in diameter, to be made in the wall opposite to which the representation is to be given. The object is placed outside, inverted, and a convex lens also placed outside. An image will be distinctly seen upon the wall, if the object be very powerfully illuminated—and in its proper position. If the object cannot be conveniently inverted, as may be imagined sometimes, two convex lenses must be employed, at distances proportioned to their respective focal distances, and the distance of the object in question. A full account of this instrument is given in the *Philosophical Transactions*, No. 38. Its only peculiarity is, that it serves in a light room as the camera obscura in a dark one.

The Camera Lucida of Dr. Wollaston is an instrument susceptible of much more varied application. It is intended to facilitate the perspective delineations of objects. In its simplest form, the camera lucida is merely a piece of smooth glass fixed at 45° to the horizon. An image from a horizontal object falling on this glass, will be partly reflected, and that in the vertical (according to the principle of equality of the angles of incidence and reflection), and an eye looking down vertically will see the image, and be able to trace it out upon paper below, from the transparency of the glass. As the reflection, however, is only once here, the image seen on the paper will be inverted. Even in this case, we can describe the outline with a pencil on the paper below.

If, again, a smooth mirror be held at $22\frac{1}{2}^{\circ}$ to the horizon, and a plane glass at $22\frac{1}{2}^{\circ}$ from the vertical, an image will be reflected doubly, will represent itself vertically, and will be shown in its true position. This, again, can be traced out distinctly with the pencil.

A practical difficulty, however, suggests itself. The image on the glass, and the pencil print on the paper, are at distances sensibly different in any ordinary instrument; hence the eye, fitted to receive impressions from the one, is not so to receive them from the other. A convex lens is employed, in order, in effect, to make the image of the glass and that on the paper coincide. The same object is attained by the use of a concave glass between the object and the mirror. This latter method is better adapted for near-sighted people.

The most usual form, however, in which the camera is found is that of a prism, which answers the purposes of the mirror and the glass. It is of this form, having the angles which B C make with the horizon, and B A with the vertical, respectively $22\frac{1}{2}^{\circ}$. The ray F G is not permitted, according to the refractive laws, to be thrown from a rarer medium into a denser, at more than a certain angle. Hence it is all reflected from G up, on B A at H, and reflected from it again up

CAM

in the line H E. Now, the prism not being so transparent as the plane glass plate, some means must be adopted of seeing past the prism. | |

One part of the eye, therefore, sees the image at H, and the other part in fact sees the plane paper below. But the laws of our mental nature will not readily permit us to imagine a double sen-

sation corresponding to the true double vision, and the paper thus appears to us to have the image of the object traced upon it. The same methods are applicable here as before, to make the image and the paper coincide as nearly as possible.

Copies obtained by the instrument of any drawings, may be either on a larger or smaller scale than the original. If the copy is to be equal in size to the drawing, the paper must be as far from the eye-piece as the object from the prism, and so in proportion.

The instrument is difficult to use satisfactorily, and many people, probably from some physical peculiarity in the visual organ, are not able to employ it well at any time. It offers, nevertheless, considerable advantages. Its small bulk and portability are remarkable. It is not in the least injured by being made small. A good instrument will pack in a box eight inches by two, and half-an-inch deep. There are, further, no lines distorted, as we shall point out to be always the case with the camera obscura, to a greater or less extent; and the field of observation, generally, may be more than twice as wide as the distinct field of the camera obscura.

Camera Obscura. Of the two optical instruments that are termed camerae or chambers, this is the more ancient. The first account of it was published in Baptista Porta's *Magia Naturalis*, 17, 6, the first four books of which were published in 1560, although the work was not completed until 1590. The invention has been claimed on very slight grounds for Roger Bacon. The construction which Porta gives is the following:—A circular hole is to be made in the shutter of a window, from which there is a good view of any prominent object, not too near, and in this hole a convex glass, single or double, (fig. 1) is to be placed, having a focus at the distance of from six to twelve feet. It should not be less than three feet at least, or the images will become very small, or greater than fifteen at most, or they will become confused and indistinct.

The diagram shows two cross-sections of a lens. The one on the left is a biconvex lens, which is thicker in the middle and tapers to thin edges. The one on the right is a plano-convex lens, which is flat on one side and convex on the other. Both are drawn with simple outlines and no shading.

Fig. 1.

Fig. 1.

and the colouring faint. Let the room be completely darkened, except through the light so admitted. At the focal distance from the aperture place a piece of paper, very white, and bend it as near as possible to the shape of a segment of a spherical surface, having the focal distance for radius. If

CAM

this paper now be fixed on a frame of this figure, and attached to a moveable stand, for the purpose of accurate adjustment to distinct vision, the apparatus will be completed. The images of all the objects outside will be seen very distinctly upon the white surface, in an inverted position, but with the greatest fidelity. Every movement in any of them will be beautifully represented on the paper.

The inversion of images is an objection which

Fig. 2

is readily removed (fig. 2). Or, if a large concave mirror be placed at a proper distance before the picture, or if two lenses be employed, in a tube which draws out, instead of the one described, we shall have the images in their natural position. Fig. 3 will explain the manner

Fig. 3

in which the image is formed. It is obtained, inverted, at the posterior focus of the lens. The ray $A'E$ passes down as $A'E$. The effect of the lens so far is a simple concentration of the rays. The circular form of the frame is the most advantageous that can be adopted, in order to have the whole picture as nearly as possible in the focus of the lens. If the paper were plane, the picture would be only distinct in the middle, shading away into indistinctness on the sides. The proportions of its parts could not be preserved. The outer rays would be dispersed more than the inner. The magnitude of the image so obtained will be in proportion to the relation between the distance of the object and the focal distance of the lens. A good deal of light shining upon the object is necessary to render the picture quite distinct, and to represent the colour clearly. The instrument is so interesting that very many

Fig. 4

CAN

portable cameras have been constructed. The one represented here is perhaps the simplest.

In the modern camera the delineation may be made, as in the original darkened chamber, upon paper bent into a circular form. Dr. Wollaston proposes that, in order to be enabled to employ a plane of paper, a meniscus lens should be employed, instead of the single or double convex, and this would, if the concave side be next the object, produce a greater lengthening of the marginal than of the central rays. This lengthening

Fig. 5

may be so adjusted to the size of the lens, and the ratio of its radii, as to render it safe to employ a plane surface.

The camera was, until recently, considered chiefly as an interesting philosophical toy. Since the invention of photography, it has become of the greatest importance. The accuracy of the pictures depended, in the first instance, on the possibility of obtaining a distinct clearly defined optical image on the photographic material, and as very many objects can only remain at rest for brief periods, this was to become possible in the shortest space of time. The latter requirement is answered partly by the sensitiveness of the chemical preparations spread over the photographic surface—partly by the intensity of the light which the camera can throw upon the object.

The improvements immediately rendered indispensable in the camera by those requirements are pretty evident. The length of the focal distance in the old cameras was not material. In the photographic camera it became of the greatest importance, at once for convenience, and from the necessity of a rapid impression already pointed out, and a concentration of light as great as possible. Achromatic object glasses were at once seen to be necessary to preserve the image clear and distinct; and above all, it became of importance that it should become possible to throw the picture accurately in its correct proportions on a plane surface, even though the field of view was pretty large. To a certain extent the latter is impossible, but science and art together have given a perfection to the photographic camera which could not have been readily anticipated. For the details of the instruments by which these requirements are now sought to be satisfied, see *Hunt's Photography*.

Canals. Artificial courses of water for sanitary, agricultural, or commercial purposes. The first kind are intended to drain marshy ground, or inundated territory; the next to distribute water from an elevated reservoir over the unwatered country; the third and most important, for the transmission of merchandise—sometimes even for the passage of ships. Some of these latter are constructed along the bed of a stream,

CAN

just beside it, because very little requires so to be cut through where the stream has worn a passage for itself. They make use of the water of the adjacent stream, merely replacing it, with its natural irregularities, by a perfectly regular stream. The canals which have *locks*, are however, more common, because capable of containing larger supplies of water in general, and requiring no original arrangement of circumstances in a locality, such as it is not always easy to procure. The lock is simply a part of the channel where naturally there would be a fall of water from a descent in the level of the country, and where two moveable folding doors, as it were, are inserted from top to bottom of the canal.

Cancer (the Crab). In the division of the ecliptic, Cancer occupies a place between 90° and 120° from the vernal equinox. It contains no very large star. It is surrounded by Hydra, Leo, Lynx, Gemini, and Canis Minor. Its sign as a zodiacal constellation is ♋ . It has for nearly 2,000 years, in consequence of precession, not been found between 90° and 120° from the equinox, i. e., coinciding with the sign. See **TAURUS**.

Canes Venatici (Hunting Dogs). A constellation added by Hevelius. On the celestial globe the dogs are represented as held in a leash by Boötes. The constellation is near Coma Berenices and Ursa Major.

Canis Major (the Greater Dog). A constellation containing Sirius (the dog-star). The constellation is found by the presence of this star, which is in the continuation of the line through the belt of Orion. The surrounding constellations are Argus, Orion, Monoceros, Lepus, and Columba Nuchal.

Canis Minor (the Lesser Dog). A constellation situated near Canis Major. The Procyon, of the first magnitude, is its most remarkable star. The constellation may be found by means of this star, which lies in a direct line between Sirius and Pollux. It is also in a line through Sirius, perpendicular to the line from Orion's belt to Sirius.

Capillarity. The manifestation of a description of molecular action between solids and liquids in contact, which disturbs the natural level of the liquid surface. The general phenomena, indeed, are familiar to every student, and may be very easily observed. Take a solid cylinder of glass, and plunge the end of it into water, the water—(provided the cylinder be clean)—will ascend all

Fig. 1.

around it, forming a curve as annexed. If a plate of glass, instead of a cylinder, be placed in the same circumstances, the water will ascend in a curved film a certain way up its sides. If a glass tube of small bore take the place of the cylinder, not only have we the phenomena just described, around its convex

CAP

surface, but within the tube itself the water rises above its external level by a considerable space. And finally, if two glass plates, fixed at a small distance from each other, have their ends immersed in the water, it will ascend to a certain height between them, and remain there apparently suspended. The quantity of liquid thus elevated varies with the liquid; nay, with some liquids it is *negative*, that is, instead of elevation we have a depression;—if mercury is employed instead of water, for instance, the foregoing phenomena are all reversed.—The study of this curious subject brings before us three distinct classes of considerations, viz., the question as to the numerical laws observed by the general phenomena;—the question as to the physical causes on which these phenomena seem to depend;—and an inquiry into the conduct of different liquids in relation to these laws and causes.

I. General Numerical Laws.—These laws express the relations between the ascent or descent of any liquid, and the bore and shape of a capillary tube or the distance between the parallel plates that bring out the same phenomenon. We owe the first experimental investigation of the subject to Gay-Lussac. The undertaking was one of great difficulty, alike because of the minuteness of the quantities that had to be handled, and the necessity of securing that these narrow tubes be in a right condition. Nevertheless, this able physicist, through effect of the nicety and judgment so honourably distinguishing French inquirers, succeeded in establishing three fundamental laws:—(1.) The elevation or depression of the same liquid in tubes of the same nature, but of unequal diameters, varies inversely as the diameter of the tube:—(2.) In the case of two parallel plates, separated by a small distance, the elevation or depression also varies inversely as the distance between the plates:—(3.) The variation of level occurring in the case of parallel plates, is half that which is produced in the case of a tube the diameter of whose bore is equal to their distance. (This latter law, however, was presented rather as a theoretical deduction from the two previous ones.)—The recent progress of physical inquiry has not established any truth more important than this—definite numerical laws, deduced from early experiments, and indicated by early theories, ought scarcely ever to be received *absolutely*, or held by otherwise than as valuable approximations; and the subject of capillary attraction furnishes no invalidation of the salutary rule. The foregoing numerical conclusions undoubtedly receive great support from their agreement with the physical theory of Laplace—a theory coincident with that of Young, and resting on the hypothesis that the volume of liquid which is raised above the level, is in proportion to the *contour of the section of the solid wall, whatever may be the curvature of this contour*. Since Gay-Lussac's now comparatively early time, new and extended investi-

gations have been projected and carried out,—among the most successful of which we must signalize those of Simon (of Metz). But undoubtedly our amplest contribution has recently come from M. Wertheim. The first account of his experiments is given in the *Comptes Rendus* for May 18th, 1857; and the superior, if not unchallengeable accuracy of his methods cannot be doubted. Wertheim has arrived at the following important general theorems:—(1.) *Two parallel planes* raise a constant volume, whatever may be their distance, and even when this distance is infinitely great:—(2.) The constant capillarity calculated from experiments with *narrow tubes*, is equal with some liquids, and with others superior, to that determined by means of two planes: it is accidental that with water the relation between these two values is equal to $\frac{\pi}{2}$, as pointed out by Simon: this relation is nearly 2 for chloride of iron, and 1 for other liquids:—(3.) *Wide tubes* give a value comprised between the two preceding ones *when the latter differ*, and equal to them *when they coincide*. This latter takes place when the liquid is *alcohol*. Now this is the only liquid by means of which the theory of Laplace was sought to be verified by Gay-Lussac. Had he made use of water, the formula would have been found utterly in fault; and Frankenheim has subsequently shown that even experiments with alcohol quite deviate from determinations by the formula, when tubes were used half an inch in diameter:—(4.) In proportion as the radii of *convex* cylinders diminish in departing from the plane where this radius is infinitely great, the volume raised continues diminishing for some liquids; for others the diminution commences at a certain limit of curvature, and increases gradually and apparently indefinitely. *Ether* seems to present nearly a constant volume. The presence or absence of viscosity does not affect this constancy or variation. Viscosity retards the movement; but when the equilibrium is established, it is not found to influence sensibly the definitive state. The most important result of Wertheim's investigation is not the mere invalidation of Gay-Lussac's numerical laws; it is that which disproves the hypothesis of Young and Laplace. Wertheim is of opinion that some new element must be introduced;—to which conception we shall again advert.

II. *On the Physical Causes of Capillarity.*—As indicated above, this part of our curious subject has not reached a condition that can be reckoned satisfactory. We shall, however, state exactly what the prevailing speculations have been, and what are their bases.—The received doctrine rests on the assumption that forces of a definite and powerful kind are exercised by molecule over molecule of any fluid mass; and that similar affections, positive or negative—that is, attractive or repellent—regulate the conduct of the molecules of liquids towards molecules of

solids, with which they are either in contact, or in a neighbourhood so close that sensibly it amounts to contact. The exact character and the peculiar energies of these forces remain matter of speculation; but over the point as to their reality no doubt can longer rest. Under article *FORCES, MOLECULAR*, the reader will find a succinct and, it is hoped, a satisfactory statement of the remarkable experimental contributions of M. Plateau to our knowledge concerning this almost evanescent subject. Let us see then what can be made out of the unquestioned existence of such molecular forces, in elucidation of these singular capillary phenomena.—(1.) Let a distinct notion be formed of the nature of the disturbing effect as regards the *level*, should these relative molecular forces induce within a tube, or between plates, a *convex* or a *concave* surface upon the liquid therein contained? It is not difficult to make the general case intelligible. *First*, let the surface be convex, as in the diagram:—This can only ensue in consequence of the particles near *a* and *b*, and of course in all similar positions, down the tube *A B C D*, being attracted towards the sides of the tube;—in other words, the phenomenon indicates an excess of action of

Fig. 2.

the solid molecular forces composing the walls of the tube, over that exercised by the liquid molecules on each other. Now, in the neighbourhood of *a* and *b* there is thus induced a lateral pressure on the part of these liquid molecules—deducting in so far (by the principle of liquid equality of pressure) from their downward effect, as determined by their ordinary gravity or weight. The column *a b, C D*, must therefore be on the whole *lighter* than it would have been but for this disturbance; and, therefore, to procure equilibrium, it must be a higher column than the external one. *Secondly*, if the case were reversed, that is, if the molecule of the liquid were driven off, or repelled by the molecule of the solid wall, its downward force must be increased exactly in that proportion, and the level of the counterbalancing column therefore *depressed*. No geometrical diagrams can offer a plainer account of the physical actions now under contemplation. But the question remains as to the *amount* of the action. As already indicated, Laplace inaugurated his elaborate theory (and Poisson in this has followed him), by the assertion that the elevating power must be the contour of the capillary surface, be that the contour of a small tube or the interval between plates. It is easy to see, however, that a doctrine so general can take no account of the special nature of the capillary or molecular forces: nor does it even really advance science, when general truths are thrown into mathematical forms that become despotic and absolute. The physical problems stirred

CAP

over by Laplace and Poisson,—problems which concern the whole important part of the question,—are again happily being stirred. Wertheim has felt it necessary to look into the phenomena from a point altogether new and fresh. He thought at first that these important anomalies might receive their solution in the admission that the angle of contingence varies with the curvature of the wall; but this is not the case. "It will be necessary, therefore," he says, "to have recourse to another hypothesis, and, I believe, to take into account the variable thickness of the liquid stratum or sheath which adheres to the solid body. This hypothesis has been suggested to me by a series of experiments which I have made upon the elevation of the solution of protochloride of iron between two parallel iron plates, which I fixed to the poles of a Ruhmkorff's electro-magnet. The lower extremities of these plates were immersed in the solution, and the values a and b for the different distances $2a$, were already known. A current was then passed into the apparatus, of which the intensity was gradually increased and measured, when the magnetic liquid was seen to rise between the two planes, often to two or three times its original height, whilst the surface acquired the curvature suitable to this new elevation; but for each intensity of magnetization the volume raised remains evidently constant, whatever be the distance of the two planes; in one word, things go on as if the constant capillarity had been doubled or tripled. We know, however, from the experiments of Brunner and Mousson, that the attraction of the liquid upon itself is not altered by its magnetization; and, on the other hand, the minuteness of the changes of form which the liquid undergoes when the polar surfaces are not immersed in it, and the fact that the augmentation of the volume elevated is independent of the distance of the planes, prove that we have not to do with an effect of magnetic attraction exerted at a distance. I think, therefore, that these facts can only be explained by the increase of thickness of the adherent stratum, an increase which may be proved directly. It will be understood, also, that as every change of temperature may cause this thickness to vary, the influence of temperature may be very different from that foreseen by the theory, only taking into account the dilatation of the liquid."

III. It is clear, therefore, that the entire subject remains unexplored. It is not likely that existing difficulties will be cleared away so long as inquirers follow the old path. It is something, therefore, to find a new one opened.—In a remarkable memoir by Mr. Waterston, printed in the *Philosophical Magazine* for January, 1858, an attempt is made to establish universal relations between the capillarity of any liquid and the latent heat of its vapour;—it following from the modern theory of heat, that this latent heat is the accurate measure of the force

CAR

of cohesion between the particles of the liquid. This inquirer, after inaugurating a special and quite original mode of experimenting, has examined the capillarity of a great many liquids in relation to this idea, and his results go very far to confirm his views. Indeed he considers it possible to compute the latent heat from the capillarity, and he has given instances, especially in the case of mercury, of the success of that method,—in proof of course of the soundness of its foundations. We may fondly hope that the whole subject will speedily be reinvestigated under a fuller and wider view of its conditions.

Capra (*the She Goat*). A small northern constellation.

Capricornus — *Capricorn* (*Goat-horned*). The tenth sign of the zodiac.

Capstan. A species of the wheel and axle, employed in lifting heavy weights of any sort, especially in the manœuvres of casting and weighing anchor.

Carnot's Function. This important coefficient may be considered as the connecting link of the phenomena produced by heat on all kinds of substances, and may be defined as the coefficient by which the difference between two temperatures if infinitely small (if only a degree Cent., or less, for instance, in practical approximations), must be multiplied to calculate how much of the mechanical value of a unit of heat supplied at the higher temperature, can be converted into work by a perfect thermo-dynamic engine, having its refrigerator at the lower temperature of the two. It is a quantity, expressive of a relationship between temperature and pressure, or between temperature and work, which has an absolute value, the same for all substances for any given temperature, but varying with the temperature in a manner determinable by experiment. It may therefore, as Professor Thomson has pointed out, be used as the foundation of an absolute system of thermometry. Carnot, the discoverer of the function, was not in possession of experimental facts by which he could determine its true form. These, however, have been recently obtained by Messrs. Thomson and Joule, by determining the changes of temperature experienced by air in passing through a porous substance from a state of high, to one of low pressure. They have thus proved that Carnot's function is approximately equal to the mechanical equivalent of the thermal unit, divided by the temperature by the air thermometer from its zero of expansion. Thus, at 0° Cent., Carnot's function = $\mu = \frac{1390}{273.7} = 5.078$ = the mechanical effect in foot pounds derivable from a thermic unit Centigrade passing from 0° Cent. to — 1° Cent. For further information, see *HEAT, MECHANICAL ACTION OF*; also, *Reflexions sur la Puissance Motrice du Feu*, &c., par S. Carnot, 1824; "Memoir on the Motive Power of Heat," by E. Clapeyron, Taylor's *Scientific Me-*

moires, vol. I., part 8; "An Account of Carnot's Theory," by Professor W. Thomson, *R. S., Edin.*, vol. xvi., part 5; "On the Centrifugal Theory of Elasticity," by Professor Rankine, *R. S., Edin.*, vol. xx.; "On the Dynamical Theory of Heat," by Professor Thomson, part 4, *R. S., Edin.*, vol. xx., part 2, and *Philosophical Magazine*, vol. iv.; "On the Thermal Effects of Fluids in Motion," by Messrs. Thomson and Joule, *Phil. Trans.*, 1854, part 2; "On the Moving Force of Heat," by M. Clausius, Berlin, 1850; Holtzmann "On Heat and Elasticity," 1845; and Helmholtz, "On the Conservation of Force," 1847.

Cassiopeia. A constellation on the side of the pole opposite the great bear, marked by five stars of the third magnitude, forming a figure like an M. These stars may be found by drawing a line from Capella to the bright star in Cygnus, which will pass about half-way between them. The figure of the constellation is that of a woman sitting in a chair, with a branch in her hand. In 1572, Tycho Brahe noticed in it a new star, first, on Nov. 11th, at which time it had a lustre greater than that of any of the fixed stars—greater than that of Jupiter, and nearly equal to that of Venus. In January, its light was less than that of Jupiter; in February and March, about equal to that of the fixed stars of the first magnitude. It went on so, diminishing in lustre, until in March, 1574, it disappeared. Tycho supposed that the same star had appeared in the same way in 945 and 1264. The authority for this is not very reliable; and comets appeared about these times, which may have been mistaken for it. Sir John Herschell suggests a possible reappearance in 1872. It was certainly more distant by far than any of the planets, for at no time had it a sensible parallax.

Castor. One of the bright stars in the head of Gemini, from which and Pollux, that constellation is named (*the twins*). It is, of the two, nearest the pole, and among the most remarkable of the double stars.

Catalogue, Astronomical. A list of stars, with their *mean* or corrected right ascensions and declinations for a given epoch. The importance of such catalogues cannot be over-estimated. They form one of the leading contributions of any age to the great subject of the *sidereal motions*. We have several old catalogues of much value; but it is only on documents constructed by aid of the instruments of recent times that future science will rely in prosecuting the more delicate and immense inquiries now opening up.

Catapulta. An ancient warlike engine adapted to throw darts against the defenders of the walls of a besieged city. In its shape and other essential points it was very much like the more recent *cross-bow*. See **BALLISTA**.

Catenary. The curve formed by a flexible cord, of which two points are fixed, and upon which no forces but gravity operate.

Usually the cord is considered as homogeneous. When the density varies in any regular way it takes a shape slightly different from that of the ordinary catenary. The equation of the curve

$$\text{is } y = \frac{m}{2} \left(e^{\frac{x}{m}} + e^{-\frac{x}{m}} \right). \text{ This curve possesses}$$

several very remarkable properties. One is that its centre of gravity is lower than that of any curve of equal perimeter and with the same fixed points for extremities. The curve, where the weight is proportioned to a horizontal projection of the part considered, is a *parabola*. This and the ordinary catenary are of chief importance in the theory of suspension bridges (*q.v.*). The properties of the catenary will be found admirably discussed in Duhamel's *Cours de Mécanique*, vol. 1.

Cathode. See **ANODE**.

Cation. See **ANION**.

Catoptrics. The science of Optics treats of the phenomena of light, and of the physical causes of these phenomena. The former we have reduced to laws, and from these laws we can deduce geometrically effects either already verified by, or, perhaps, anticipatory of, experiment. The question of the physical constitution of light has been long debated, and has only been recently put upon a satisfactory basis. With the phenomena alone, the present article has to do.

The phenomena of geometrical optics are principally three—the phenomena of light passing through a homogeneous medium, or through a vacuum—of light passing from one medium, or from vacuum, into vacuum or another medium—and finally, the phenomena of light incident upon a medium at its surface, and thrown back from its surface as incapable of passage.

The first of these may be treated of under optics properly; the latter two, which form the most important departments of geometrical optics, are generally designated the sciences of *dioptrics* and *catoptrics* respectively. The latter is the subject of the present article.

The first important theorem of catoptrics is this, that the incident and the reflected ray are situate in the same plane with the perpendicular to the surface, from which the reflection is made, at the point of reflection. Thus, if a ray be incident upon a floor, and if we draw a perpendicular to the plane through the point of incidence, and apply, suppose a piece of paper to the two lines, so as just to lie upon them, the reflected ray would be reflected somewhere in the plane of the paper.

This, however, gives us but little information. It tells us something that the ray cannot do,—viz.: turn to the one side or the other; but it does not give any definite idea of its course. This is supplied by the next law, that the course of the line of reflection in the plane so fixed is determined by making, with the perpendicular to the surface of incidence, on the same side with

CAT

the incident ray, an angle, equal to that made by it with the incident ray.

Two definitions which may here be given, will enable us to express this law very simply. The angle of incidence of a ray of light is the angle which that ray makes with the perpendicular to the surface of the substance on which it strikes. The angle of reflection is the angle similarly made by the reflected ray.

The laws, therefore, of catoptrics may be expressed thus:—When a ray of light is incident upon a reflecting substance, the reflected ray is in the same plane with the incident ray, and the angles of incidence and reflection are equal.

Assuming then, the perfect exactness of these laws, we shall see that catoptrics is not at all concerned with the non-homogeneity of ordinary light rays. In other words, though rays do differ in essential qualities, and though white light is made up of rays different in nature, it will not be decomposed or separated by reflection into rays of different colours. This one law, of the equality of the angles of incidence and reflection, holds for all kinds of light. Hence rays which, though really different, come mingled together on a surface, will leave it undecomposed. This is a most important result, and at once relieves us from the necessity of instituting inquiries upon the various reflective (like refractive) powers of different light rays. We shall now proceed to detail some of the more important propositions of catoptrics.

And the first proposition we shall state, is this;—when a number of parallel rays fall upon a plane reflecting surface, the reflected rays corresponding to them will also be parallel. This will be clearly seen by any one who sets a number of rods parallel to one another, and inclined to a floor, and then bends them over until they shall be again inclined equally to the floor. It will be readily seen to be in strict accordance with the geometrical laws of plane surfaces, thus:—the planes containing each incident ray, with its corresponding reflected ray, have two lines, which meet one another in each parallel, namely, the perpendicular to the original plane and the original rays. It follows, therefore, that the planes themselves are parallel. Hence, as the reflected rays make equal angles

Fig 1

straight rods at the two points of incidence on the floor to serve for the perpendiculars.

Our next important proposition is the following—*that if a pencil of light diverging from, or converging to a point, fall upon a plane mirror, the re-*

CAT

flected rays will have the appearance of diverging from or converging to a point at an equal distance on the opposite side of the mirror. Thus, let a number of rays, QA, QB, QC , diverge from the

Fig. 2

point Q , and fall on the mirror at A, B, C , they will appear, when reflected, to diverge from the point q , at an equal distance from the mirror, at a distance on the other side equal to NQ . Draw AM , and let BA be produced through A to meet QN produced in q . Then $\angle QAN = \angle RAB$ (by the reflective law), and $\angle RAB = \angle N A q$ (I. 15), therefore, $\angle QAN = \angle N A q$. Hence the two triangles NAQ, NAq , have one side common and two similarly situated angles equal, and are therefore in every respect equal— NQ being equal to Nq . The reflected ray AR appears, therefore, to come from q . This proof determines, then, the length of Nq , and it has been shown equal to NQ by a method equally applicable to the other rays as to QA . Hence all the rays will appear to come from q , and the proposition is proved.

When we have two or more plane mirrors at which luminous rays are successively reflected—as for example, a second mirror, from which the reflected rays in the last figure will be a second time reflected; and a third, from which three will be again thrown back; and a fourth and a fifth, and so on; the point of divergence or convergence of the rays after the second reflection will be found, simply by supposing the focus of the first reflected rays to be a real point from which really emanate luminous rays. Reflected light is reflected, just like light coming from a luminous point, and has lost none of its properties in this kind. It has lost none of its component rays, as we have already proved. We can, therefore, apply the principle already demonstrated for unreflected light, in the case of light reflected from a plane mirror, again reflected in another, and that perhaps re-reflected from a third and fourth.

It is frequently an interesting point to discover the amount of deviation of a ray of light which has been reflected at each of two plane mirrors, in a plane perpendicular to the line of their intersections.

Let SA be the ray, so incident on the mirror A , and reflected back a second time from B . The

angle D is called the angle of deviation, and its amount is required.

Fig. 2.

The angle $\angle SAB = \angle ABD + \angle ADB$. Now, $\angle SAB = 180^\circ - 2\angle BAC$ and $\angle ABD = 180^\circ - 2\angle ABE$. Therefore, $180^\circ - 2\angle BAC = 180^\circ - 2\angle ABE + \angle ADB$. Hence $2\angle ABE - 2\angle BAC = \angle ADB$, but $\angle ABE - \angle BAC = \angle BCA$. $\therefore 2\angle BCA = \angle ADB$. That is, the angle of deviation is equal to twice the angle of inclination of the two mirrors.

An investigation exactly similar would make it easy to find the angle of deviation after three or four, or any number of reflections from plane mirrors—all the reflections being made, however, in the planes, to which the successive lines of intersection of the first and second, of the second and third, of the third and fourth mirrors, are perpendicular.

This proposition has been grounded on the hypothesis that the mirrors are plane. It is evident, however, that as no part but a very small part, in fact, the point of incidence, of the mirror is at all concerned with the reflection of the ray, the proposition would hold equally good whether we have plane mirrors or not, provided only that a very small space, indefinitely small, coincided in direction with the planes, whose angles of inclination we consider in determining the angle of deviation. It is evident that the mirrors may be of any form which will permit the reflection of the rays so, and which will not be so bent as to catch one of the reflected rays again after reflection. We may have them, therefore, curved mirrors, of any form whatever, and the angle of deviation of any ray after two reflections from curved mirrors will be double the angle of inclination of the two planes which touch the mirrors at the points of incidence of the rays upon them. This idea of tangent planes will be readily conceived, if the reader take any ball, and apply a plate of glass or paper, so as just to touch it in a point without being itself bent, or the ball indented by pressure. He will easily see that there is only one direction in which he can apply the plane of the paper or glass to the ball, so that it will just do so, for each point of application, and so, there is only one direction in which he can apply the plane to the curved mirrors already described, and therefore, the angles of inclination of each successive pair of planes are quite determinate quantities.

The law of reflection can therefore be applied to the case of curved surfaces, by considering them as coincident with plane surfaces, tangents to them, or having for an indefinitely small space the same direction as them.

Having established this principle, then, we are able to apply the law of reflection to the case of

curved mirrors, and to deduce the various effects certain to result in that case.

We shall just examine the case of rays reflected to one point, and crossing one another's directions in that point. This, though not so important as the corresponding problem in dioptrics, the discovery of surfaces of accurate refraction—at all events, for the purposes of the optician—is sufficiently important for other purposes to deserve attention.

If a pencil of parallel rays fall upon a concave parabolic reflector, in a direction parallel to the axis of the body (the line in its centre is called the axis), the rays will be reflected so that these lines of direction, after it, shall pass through one point. Of this proposition we can offer no proof. It rests upon the assertion, itself demonstrable in the higher mathematics, that the perpendicular to a parabolic surface, at a given point, bisects the angle made by a line through it parallel to the axis, and one from it to a point, fixed for any given parabola, and called its focus.

A similar surface of accurate reflection will be found in an ellipsoidal shell, on the interior of which rays fall, diverging from the one focus of the ellipsoid, by which these rays will be reflected in lines all passing through the other focus of the shell.

Another still might be found in a hyperbolic reflector, from one focus of which rays proceed, falling on the convex reflecting surface, which will send them back to the other focus.

If, in these cases, the mirror be silvered on the one side instead of the other, and if the same rays, continued indefinitely, be imagined to fall upon this new reflecting side, we obtain a series of propositions almost identical with those already given, and having application to convex reflection of the shapes just specified. Thus, if a pencil of parallel rays be incident in a convex parabolic mirror, parallel to the axis, the reflected pencil will diverge from the focus of the parabola.

This proposition, and the one corresponding to it, are by far the most important of those now submitted. They apply to the cases most frequent in actual nature—of solar, astral, and lunar rays. These, coming from a great distance, diverge so little, compared with that distance, that they may be considered as perfectly parallel. If, therefore, a system of parallel rays fall on a parabolic mirror (as for example, any of the rays specified), they will be reflected to the focus, if they fall upon the concave mirrored side; and from the focus, if they fall on the convex mirrored side.

We find thus then points of accurate reflection in various circumstances, and it is clear that, as we are able to describe as many ellipsoids and hyperboloids as we choose when the true foci are given in each case, we might make a mirror of any particular curvature that we might want, capable of reflecting rays of light coming from a

given point on to another given point. But the construction of such mirrors (paraboloids, ellipsoids, hyperboloids) is very difficult, and they are therefore very expensive. On the other hand, spherical mirrors are constructed with comparative ease. If then, we can obtain such mirrors capable of producing all the effects due to the more expensive kinds, even approximately, it will be convenient to adopt them. It becomes, therefore, necessary to investigate the properties of spherical mirrors.

And first, with respect to the more frequent though less general case of parallel rays incident on a reflecting surface.

Let OA pass through the centre, parallel to the pencil of rays which we consider, and let SP

Fig. 4.

be one of these rays. Then the tangent to the surface BAF , is like all the tangents to circles—perpendicular to the radius OP . If, therefore, we consider the circle as equivalent for a small distance to a thin plane mirror, coinciding with the tangent, on whose surface the incident ray SP falls, we shall have, by the law of reflection, the angles SPO , QPO equal (angles of incidence and of reflection). Now, $SPO = POQ$. Hence the angles POQ , QPO are equal, and the triangle PQO is isosceles (having the sides PQ and OQ equal).

We might, by trigonometrical methods, find the length of the line OQ in any given circumstances. We shall confine ourselves to some more special cases. If the angle POA be very small, which it will be, for a given length PA , if the radius be very large, the figure PQO becomes very nearly a straight line. The three sides come to coincide. The proposition just established does not at all depend, however, upon the size of POA , and will still hold good, therefore, in the case now imagined. If we suppose the triangle becoming indefinitely, or even infinitely near to a straight line, from the increase of OA , or the diminution of PA , the proposition will continue to be true. In this case, however, the sum of PQ and OQ will be indefinitely near equal to PO , and they may, therefore, each be considered as equal to its half, or to the half of OA which is equal to it. Hence the point of nearly accurate reflection of parallel rays falling upon a circular mirror, having a very small angular range (*i.e.* representing a very small *aperture at the centre*), will be the point of bisection of that radius of the mirror which is parallel to the pencil of rays. AF is called the prin-

cipal focal length, as being the focal length which serves for the greatest number of rays; all of those which correspond in description to SP , with regard to the part of the mirror on which they fall, being equally reflected in directions very nearly passing through F . The line AF then is equal to half the radius of the circle.

If AP represent a moderate angle at the centre O , QO will be the half of the sum $QO + QP$. This sum is greater than PO (I. 20) or OA , and QO is therefore greater than the half of OA , or than OF which is equal to it. If the angle POA become larger than 60° , the angle OPA (joining PA) would be less than 60° , and the ray would be reflected on to the mirror again before passing so as to cut OA . The same laws of reflection would apply to this case, which, as specula or mirrors are not usually made which correspond to a central angle of 120° (twice 60°), does not very often occur.

The caustic curve (see CAUSTIC) is an effect of the law of reflection also. When a reflecting curve is exposed to the parallel rays of the sunlight, a luminous space, as in fig. 5, with a curved outline, is made by means of the reflecting lines. The space is that on which the re-

Fig. 5.

flecting lines mostly intersect, and in which, therefore, there is a greater concentration of luminous rays.

The more general case, of the refraction of luminous rays by spherical mirrors, when these rays diverge from a point, remains to be considered. We shall take the mirrors as concave to the ray, and shall find that by altering the signs, and affixing different values for the various quantities specified in the question, we will be enabled to comprehend in the solution of this case all the cases of spherical mirrors.

Let PAP , be a section of the mirror, and let QOA be its axis, Q being the luminous point, from which diverging rays, QA , QP , fall upon the mirrored surface. Let F be the principal focus, as already defined, and O the centre of curvature of the surface. Let QP also be one of the incident, and QF the corresponding reflected ray.

Then, as before, QPO is the angle of incidence, and OPQ the angle of reflection, and since these are equal $QO : QO :: QP : QP$ (VI. 8). This expression is universal, and suitable trigonometri-

Fig. 6.

cal expressions might be found which would give the value of the distance $q o$ in terms of the angle $P O A$ (the fixed angle of the lens), and of the instance $q O$, and the radius $O A$. We shall limit ourselves to a less comprehensive case. Suppose the arc $P A$ to subtend an inconsiderable angle at the centre, which may be the case either by $P A$ becoming itself very small compared with $P O$, or inversely by $O A$ becoming very large compared with $P A$. Then $q P$ and $q A$ may be taken as in fact equal, and so also $q P$ and $q A$. In fact, in that case, each pair of lines approach very closely to each other, and therefore become very nearly equal. The proportion already established, and always maintained, as not at all dependent on the relative magnitude of $P A$, will now become

$$q O : q O :: q A : q A$$

Calling $q A = u$ (the perpendicular distance of the point q from the mirror), passing in this case through the centre O , and $q A = v$, and $O A = r$.

We get

$$u - r : r - v :: u : v$$

$$\text{and } \frac{u - r}{u r} = \frac{r - v}{v r}$$

$$\text{or } \frac{1}{r} - \frac{1}{u} = \frac{1}{v} - \frac{1}{r}$$

$$\text{and } \frac{2}{r} = \frac{1}{v} + \frac{1}{u}$$

$$\text{Now } \frac{r}{2} = f$$

$$\text{Hence, taking reciprocal equality, } \frac{2}{r} = \frac{1}{f}$$

$$\therefore \frac{1}{v} + \frac{1}{u} = \frac{1}{f} \text{ in the case when the arc}$$

$P A$, becomes by any method, small in comparison with the radius, and hence subtends a small arc at the centre of the circle.

It is quite evident that as a ray, $q P$ would have been reflected to Q , the same proof, and therefore the same result will apply, if q be supposed the luminous point, to the rays from which, we desire to find the point of accurate reflection.

This expression serves, then, in the case of rays falling upon a concave mirror. If, however, the mirror be turned in the opposite direction, silvered on the opposite side from that where it was silvered before, the radius changes its sign—that is, we might imagine a mirror with a gradually diminishing radius of curvature, having the centre of the circle of curvature constantly between Q and A , and constantly approaching A , until the radius becomes $= 0$, and we may imagine the same process to continue, the centre to keep still moving onwards in the same direction, passing A , and being supposed, in order to suit algebra, which does not take direction into account, to become less than nothing, or negative. Similarly, the point q , going along with the

radius, and keeping on the same side of A , makes $q A$ or v also negative, while $q A$ or u remains as before.

In the ultimate equations, however, o we do not find r , but f , which is evidently

Fig. 7.

affected by the same circumstances, and of the same sign. Therefore

$$-\frac{1}{v} + \frac{1}{u} = -\frac{1}{f}$$

$$\text{and } \frac{1}{v} - \frac{1}{u} = \frac{1}{f}$$

The same remark, already made in the case of concave mirrors, that if q be the luminous point, the proof and the result might be alike employed for determining the focus of accurate reflection Q , may also be repeated here.

Taking now the two equations,

$$\frac{1}{v} + \frac{1}{u} = \frac{1}{f} \text{ for mirrors concave to the in-}$$

cident rays,

$$\text{and } \frac{1}{v} - \frac{1}{u} = \frac{1}{f} \text{ for mirrors convex to them,}$$

let us proceed to examine the various cases which occur:—

$$\text{Let } u = \infty \text{ (become infinite), then } \frac{1}{u} = 0,$$

$$\text{and in either case } \frac{1}{v} = \frac{1}{f} \text{ and } v = f$$

That is, that in the case of parallel rays incident on a mirror, either convex or concave to their direction, the rays are reflected to, or are reflected so as to appear coming from a point in the axis of the mirror, within its completed circle,

$$\text{and at a distance from } A = f = \frac{r}{2}; \text{ as we have}$$

already shown in considering this special case.

If u be greater than r , then in the first case $\frac{1}{v}$ is greater than $\frac{1}{r}$ and less than $\frac{1}{f}$ and v is less than r and greater than f .

In the second case $\frac{1}{v}$ is greater than $\frac{1}{f}$ and therefore v is less than f . In the first case, then, q will lie between r and o (fig. 6), if q lie on the opposite side of o that A does. In the second (fig. 7), q will lie between r and A , if A be greater than r . In this second case, if u be any positive quantity, however small, that is, lie at all on the opposite side of A that o does, the same consequence will hold.

If $u = r$, then in the first case, $\frac{1}{v} = \frac{1}{r}$, and $v = r$ (that is, all rays coming from o will be reflected back upon o)—as we should have expected, seeing that the luminous rays, all being radii, will all be perpendicular to the surface of the mirror.

CAT

If $u = r$, in the other case, $\frac{1}{v} = \frac{3}{r}$ and $v = \frac{r}{3}$, or $q \Delta = \frac{O \Delta}{3}$, if $\Delta Q = \Delta O$.

If $v = r$ this case, in $\frac{1}{u} = \frac{1}{r}$ and $u = r$, or the rays are reflected to the luminous point, as before. This case is, in fact, exactly the same as that in which we have already got the same result, because the reflecting substance will now be concave instead of convex to the incident rays.

If u be less than r , and greater than f , then $\frac{1}{v}$ is less than $\frac{1}{r}$ and v is greater than r , in the first case. That is, if the luminous point come to occupy such a position as q , the point of accurate reflection will pass along towards q —a result which we have already seen cause to anticipate. In the second case, we would obtain a result exactly identical with that already pointed out, when u is positive at all. If q were in this case to change its position, giving a negative line, we would be brought back to the case already considered, for concave mirrors.

If, again, $u = f$, then, for concave mirrors, $\frac{1}{v} = 0$, and therefore v is infinite. This is precisely the application of the proposition that in every case, if either of the points q or Q be the luminous point, the other will be that of accurate reflection, to the case of parallel rays—for the reflected rays, converging to a point at an infinite distance, are, in fact, parallel. If $u = f$, in the case of convex mirrors, the same result will be obtained as is got when u is taken positive. If $u = -f$, for this case—we are brought back to the case of concave mirrors.

If u be less than f , then $\frac{1}{v}$ is negative, and v is also negative in the first case. That is, if q (fig. 4) be situate between F and Δ , the rays will be reflected as if diverging from some point on the side of Δ , opposite from F and Δ . If (fig. 7) u be less than f , we have precisely this case, and if u be less than f , we find a particular case of u being positive—a supposition already examined.

If $u = 0$, then, in the first case, $\frac{1}{v} = -\infty$, and if $u = 0$ in the second case, $\frac{1}{v} = \infty$, and $v = 0$.

If u become negative in the first case, we revert to the case of convex mirrors, and in accordance with that, find the formula giving u positive and greater than f . If it become negative in the second case, we obtain the formula for concave mirrors instead of convex ones.

It is interesting to deduce the expression for

CAT

the case of plane mirrors from the formulæ just found. They may be considered as small parts of circles of no curvature, and infinite radius, because it is quite evident that the nearer a circle becomes to a complete plane in any large part of it, the larger its radius must get. Suppose, then, $r = \infty$, then $f = \frac{r}{2} = \infty$ also, and $\frac{1}{v} + \frac{1}{u} = \frac{1}{f} = \frac{1}{\infty} = 0$, $\therefore \frac{1}{v} = -\frac{1}{u}$ and $v = -u$ that is, the point of accurate reflection is on the opposite side of the mirror from the point of divergence of the rays, and at an equal distance from the mirror. We should have had the same result by taking the other formula for convex mirrors $\frac{1}{v} = \frac{1}{u}$ and $v = u$; seeing that the positive values of v and u are now obtained by taking them on the opposite sides of Δ .

It is important to notice that in every one of the special cases considered, it was only necessary to take u as positive in the one case, and negative in the other, to make the two cases coincide. In fact, we have seen that the two cases differ by having the signs of two of the quantities different. When the sign of the other also becomes different, we get a formula something of the form $-A = -B$, which is readily convertible into $A = B$, the original expression. Taking it geometrically, we see, indeed, the same thing. The whole system of mirror, rays, luminous point, is merely transferred to a new position in space, and as physically it makes no difference in the results what position in space a system may occupy, we should expect this total change to restore the exact equivalence of the formulæ. A physical change would be generally wrought in the results of any system, by some relative alterations of positions; but when the whole position alters, maintaining all the while its internal relations, there is no difference of results.

An important proposition, which is of great value in enabling the student immediately to deduce many of the results just given, and in concentrating them into one, is the following. The focal length is a mean proportional between the distances of the conjugate foci from the principal focus.

Taking the proportions already obtained—

$$u - r : r - v :: u : v$$

$$\text{or } u - r : u :: r - v : v$$

we get, by composition and division $2u - r : r :: r : 2v - r$

$$\therefore u - \frac{r}{2} = \frac{r}{2}$$

$$\frac{r}{2} = v - \frac{r}{2}$$

$$\text{or } \frac{FQ}{FA} = \frac{FA}{FQ}$$

and therefore $FQ \cdot FQ = FA^2$

If we remember that, as has been shown in the various cases which we have specially examined, the conjugate foci always lie on the same side of the principal focus, the proposition will enable us in any case very speedily to arrive at the results which we may desire.

It is essential to remember that in all the cases just examined, and in all the propositions now established, the arc of the mirror is considered as being very small, compared with the radius of the arc. If it be not so, these propositions will not hold good, and, in fact, there will be no point of accurate reflection.

Caustic. When a number of rays from a point are reflected or refracted from a reflecting or refracting surface, the line which would be made up by the series of intersections of the successive reflected or refracted rays is called the *caustic curve*. For example, if a series of luminous rays, sent from a point so distant that the rays are practically parallel, be reflected from a semicircular rim, the curve $x y z$ represented in the figure will be the *caustic curve*. Suppose two

very near rays, such as the rays A and B, intersecting each other when reflected in the point C, then the curve is the line made up by an infinite number of such points. It will be practically exemplified if we place a semicircular rim of tin upon a table exposed to the sun's rays. The curve will be the line of division between the bright space on the table and the dark one. It will, indeed, be evident, by producing the reflected lines, that no point beyond the line of the curve can get more than half of the light reflected from the one-half of the semicircle, while points between the rim and the curve are exposed to the light reflected from the whole.

We may have a caustic formed in the same way for any reflecting or refracting surface, exposed to light from points situated in any position. The theory of caustic curves is very interesting. It was first discussed by Tschirnhausen. Malus treats very fully of it in his *Theorie de la Double Refraction*.

The special name given to the caustic of reflection is *catacaustic*, sometimes simply *caustic*, and it is this that is employed above;—the curve of refraction is called the *diacaustic* curve ($q v$).

• **Centaurus (The Centaur).** A southern constellation which scarcely rises in our latitude.

It is situate near Ara, Lupus, Libra, and Virgo. The stars α Centauri and β Centauri are of the first magnitude. Sometimes it is made one constellation along with Lupus, and it

would appear that various of those which we have mentioned have been united with it.

Centering. The subordinate arches of wood or slight stone-work, employed for the convenience of the architect in laying the materials of our larger bridges, are called *centering*. They depend equally with the bridge upon the mathematical principles of the arch. See BRIDGES and ARCH.

Centigrade. See THERMOMETER.

Central Forces. A body under the action of any one force moves uniformly in a straight line. The law of *Inertia* declares that a body moving so, will, if not interrupted, continue to move so for ever. If then a body move either with changes of velocity or changes of direction, there must be some new force, the introduction of which has produced these. If, for instance, a body moving at a uniform rate increases or decreases its velocity—as a steam-engine—we know that additional force has been exerted in the one case, and that contrary forces have been brought into play in the other. If, again, as in a ship tacking, or a projectile falling, a body change its direction of motion, there must have been a like introduction of new forces. The theory of central forces in its elementary stage treats chiefly of the latter case.

Suppose that a body, moving along at any rate, receives a shock; it will proceed to move in a new direction (the new direction being a straight line, though not the same as before). If, again, it receive another impulse, it will again change its direction, and so on with a third or fourth impulse. We may readily suppose a series of such impulses acting so that the primitive directions and lines of motion shall be restored, and that the body be thus made by the compounding of each successive motion with the result of each new impulse, to describe the circumference of a polygon. If we suppose these impulses communicated in a very rapid succession, we shall have a polygon with a constantly increasing number of sides, and if we suppose them added at infinitely small intervals, we shall have a curve. All motion then, in a circle, depends upon such a communication of successive impulses at infinitely small intervals of time—each impulse driving the moving body in a direction different from that in which it moved previously.

In some cases of curvilinear motion, indeed, no such impulses are at first discerned. If, for example, a bullet be attached to a string, and made to rotate round it as in a sling, there is a curvilinear motion produced, yet we only see at first sight the one force of the *impulsion* which we give the body. If, however, we increase the velocity of the bullet or its weight, we shall find that the string is broken. Now, the bullet moved

perpendicular to it in every case, and as it was quite free so to move, we should not expect that this impulse had been the cause of the breaking. In fact, at every point, the ball did move perpendicularly to the string, but it did not continue to move in the line thus given it at any point, but diverged towards the centre. The ball at A would have moved along to C in a given time, whereas it does move only to D. Supposing then the lines considered to be very small, there must have been a downward force acting upon the string, and pulling it to the centre equal to AE . The string remaining straight, there has been an equivalent force pulling the string from the centre called into action. This force is the tension of the string; and simply means the force, which its cohesive properties enable the string to resist, without being broken. If this force AE be so great, that the string cannot sustain the opposing force of its equivalent, the string breaks, and the body flies off. This then is called the *centrifugal* force. The *centripetal* force is simply the adverse force which acts upon the body to prevent its moving along the tangent AC .

The *centrifugal* force (as it is called) varies as the square of the velocity of the body at the moment, and in the inverse ratio of the distance from the centre. (In the case of bodies moving in curves not circular, the centre spoken of is that of a circle which would just touch the curve at the point.) As the velocity at any point varies as the radius inversely, the centrifugal force varies as the inverse cube of the radius.

An interesting illustration of the centrifugal force will be obtained, if we set a circular ring of spring steel upon an iron bar, which is free to rotate in its socket, and cause violent revolution.

The figure will represent the result. The middle and extremities of the circle perform their revolutions in the same time. Hence the velocity, and therefore the centrifugal

force is very much greater at the former than at the latter points. The spring then tends to whirl off the rod, and most where the centrifugal force is greatest. There is thus a pressure generated, which bulges out the ring as represented. This is shown in a large scale in the great terrestrial inequality of the polar and equatorial diameter. The line of the poles corresponds to the line of the rod, and the ring may represent a diametral section of the earth's mass. The centrifugal force is at no point sufficient to overcome the attraction of the earth's mass, and so all motion must be along its surface. The centrifugal force, however, at the pole is nothing, or very nearly, and there is therefore a pressure towards the centre due to the whole attraction. At the equator, again, there

is a very great centrifugal force, arising from the earth's rotation round the poles. A particle at the equator describes its 25,000 miles in the same time as one near the poles describes one mile of circuit. Hence, not the whole attractive force, but that, less by this centrifugal force, presses the mass at the equator to the centre. The earth, then, is as a ball of soft matter unequally pressed; it will be squeezed out in those places where the pressure is least. Therefore, it is higher at the equator than at the poles. If the velocity of the earth in its rotation round its axis were about seventeen times as great as it is, this effect would become so marked that a body at the equator, not retained by cohesive force at the surface, would fly off. There is a diminution of rather less than $(\frac{1}{17})^2$ in the weight of a body at the equator and at the poles. See EARTH, DENSITY OF THE, and EARTH, FIGURE OF THE.

Centre of Gravity is that point of a body which, being supported, the whole body will remain at rest, although subjected to the action of gravity.

In this definition, it is assumed that such a point does exist—that there is some point in every body, or which may be supposed connected with it, which, being supported, the whole will be so also. This assumption is made upon the following ground:—All bodies may be imagined to consist of a large number of particles of matter, connected by cohesion. Suppose, then, to take the simplest case, a body composed of the

Fig. 1.

two particles A and B, connected together, and both acted on by such a force as gravity. Then, as gravity may be supposed to act for any average distance AB , constantly in the same direction, imagine AP and BQ to represent its line of action. The force upon A and B will be proportional to their masses, and therefore they will just fall with the same speed, and preserve throughout their relative position. B might be considered as made up of (say) four pieces, each equal in mass to A, and each piece would then be acted on by a force equal to that upon A, and the four pieces, in falling, would move all together, and would move just as A moves. Hence, if AB be a material connection, suppose an infinitely thin rod, so as to have no sensible weight of its own, it would not be at all twisted from its original position with respect to the horizon: so that exactly the same motion would be produced upon a mass equal to A and B together,

by a force equal to the sum of those acting upon A and B. If we suppose, then, a force equal to that with which gravity would act upon A and B together, acting somewhere and producing equilibrium in the whole system,—we shall obtain that which we can substitute for A and B separately. Now, it is evident that this force must act between A and B. In any other case A and B would fall round the line of its direction. If B be the heavier (say four times), it will have four times the tendency to fall round the line of force in any case that A has; but the velocity which gravity produces is the same for A and B. Now, in order that the line A B may remain steadfast, the spaces described by B and A in falling round the line of application of this force, would be just in proportion to the lines B C and A C (C being its point of application). Hence, A C must be just in the same ratio to B C that the force applied to B is to that at A (see LEVER); and if it be so, equilibrium will be produced. If, then, the point C be supported, there will be no motion, and the actual motion of A and B might be replaced by a motion of their sum at the point C, under the gravitating influence due to the united weight.

In all this we have not required to consider what position A B occupied with regard to the direction of gravity. It therefore comes to the same thing, whether we imagine it oblique or not. If then, we have merely A and B, with the same weight at the same distance, C will always be their centre of gravity. There does exist, therefore, in the case of *two* material points connected into one body, a point between them which, being supported, the system remains at rest, and upon which the strain is equal to the combined weights.

But as the same thing may be shown regarding any number of points, it may be concluded that in every given body there exists a point which can be determined, (and which remains in the same place in the body as long as the body remains the same, whatever position it may assume,) at which the gravitating forces which really act upon all the individual points of the body may be supposed concentrated, when we wish to consider the body either in motion or at rest. In fact, we may suppose, (theoretically) the body removed, and a heavy material point weighing the same as the body substituted in its place.

The stability of a body (see STABILITY) in its position of equilibrium is that property by which, if disturbed, it tends to return to rest in its original position. If the centre of gravity be supported from above, any disturbance would cause the body to oscillate like a pendulum round the point of support, ultimately, (from friction, resistance of air, &c.) coming to rest. If the point of support be very far from the centre of gravity, the body will rapidly return to comparative rest, under the same disturbing forces as would have caused a protracted motion had the

two points been near. If the support be obtained by holding the centre of gravity itself, as by pushing a fixed rod through it, the equilibrium will be preserved in any position which the body may assume. There will be no tendency, in fact, to fall round the point of support. If, again, that point be below the centre of gravity, as when a body rests upon a table, then the equilibrium will be unstable, if there be only one point upon which the body rests. If the base be considerably extended around it, small disturbances will remove the centre of gravity, indeed, but the vertical through it will still fall within the base, and gravity will restore the body in some cases to its original position, in some not. If a vertical through the centre of gravity fall within the base, however, there will be equilibrium. This is strikingly illustrated by the hanging tower of Pisa, a building like that below, with its centre

Fig. 2.

of gravity as shown, and the vertical through it, falling within the base. If we suppose another storey added to the tower, the centre of gravity might be conceived to be raised till the vertical would just fall at the edge. In this position there would be equilibrium, but the least horizontal force coming against it would upset it (a slight breeze for instance). If another storey be added to the tower, the vertical from the centre of gravity would no longer fall within the base, and the tower would fall. We can explain these successive results by supposing the tower removed entirely, and the weights collected at the various points which are successively the centres of gravity.

It remains to describe the method by which the centre of gravity may be found.

In regular bodies it is very easy to see where the centre of gravity will be. Thus, in a circular or square plate of homogeneous matter, the centre of gravity will be the centre of the figure, or rather, if we imagine it cut in the middle by a section parallel to the two surfaces, it will be the centre of that section. In a homogeneous cube or sphere, the centre of the figure would again correspond with the centre of gravity. In short, wherever we have a regular figure made up of a series of pairs of points, corresponding in weight and in distance from a point of the

figure, that is the centre of gravity. This conclusion, it will be evident, includes bodies not quite homogeneous. A sphere, for instance, made up of concentric shells might be composed of any kind of matter, and the shells of any different kinds of matter, such as iron, brass, tin, &c., if each shell remained quite homogeneous.

Usually, the masses with which we have to deal are not so constructed. If their surfaces conform to any law, and their density varies according to any other law, depending upon position, we may suppose mathematical solutions of the problem. If, as in most ordinary bodies we have a mere agglomeration of particles, we require to determine the centre of gravity by experiments in each case.

Let the body be suspended by a string, and allowed to find its position of equilibrium. Then, as we have already pointed out, the equilibrium must be due to the action of some force counterbalancing gravity. That force is the tension of the string, and this must therefore be directly opposite to the line in which gravity acts on the body. This line passes through the centre of gravity, and so therefore must the direction of the string. Mark the direction of the string through the body. Suspend it by another point, and we shall have a second line of direction passing through the centre of gravity of the body. The centre of gravity is therefore a point through which both of these lines pass. But as the lines can only both pass through one point, that point must be the centre of gravity.

It is quite indifferent what points we select as those by which we may suspend the body. There is only one centre of gravity in every body, and the lines will always intersect as we have shown in that one point.

If finally, we have two or three bodies united into a system, and of each of which, perhaps from their symmetrical figures, we know the centres of gravity, we may find that of the whole system by a method already indicated. Imagine the bodies removed, and heavy points with weights equal to them, placed at their centres of gravity. Then the centre of the first two will be found by dividing the line joining them into parts in the ratio of the weights, the lesser being next the greater weight and vice versa. We can suppose them removed now, and a mass equal to their sum placed at the point of division so found. This combined in the same way with the third would give the centre of gravity of the three, and a similar process might be pursued for any number, until we obtain finally the centre of gravity of the system.

Centre of Gravity; Conservation of the Motion of. One of the most important among general theorems in Rational Mechanics; first demonstrated by Newton in his fourth Corollary to the Third Law of Motion, and afterwards generalized by D'Alembert. It may be expressed as follows:—*The mutual action of the different*

bodies of a system on one another, cannot, whatever be the nature of that action, alter in any wise the state of the centre of gravity of the system; so that, if the only accelerating forces influencing the system be these reciprocal actions; or, what is the same thing, if the external forces affecting it be not accelerating, but instantaneous forces, then the centre of gravity of the system must either remain motionless, or move in a straight line. The singular advantage of the foregoing theorem is this;—however complex the system may be of which one is treating, or whatever the form of the body whose motions are being investigated, the problem concerning the motion of its centre of gravity is as simple as if we were treating the elementary case of the motion of a point. And as all movements of translation appertaining to any system, are virtually movements of its centre of gravity, it follows, that when considering any such problem, we may neglect those effects of the mutual action of the bodies composing it, the determination of which generally constitutes the chief difficulty of Dynamics.

Centre of Gyration is the point at which, if the whole mass of a body rotating round an axis or point of suspension were collected, a given force applied would produce the same angular velocity as it would if applied at the same point to the body itself.

Suppose, for example, a wheel pushed in any direction by a certain force, it will only act originally at the point of application. By virtue of the rigidity of the body, however, its action will be transmitted to the whole wheel, and a certain motion produced. Now, if we imagine the mass of the wheel collected at the centre of gyration, and if we imagine the same force acting on the same point, which now must be supposed to be without weight, but rigidly connected with the mass at the centre of gyration, the motion produced would be exactly the same as that of the point corresponding to this in the wheel. The angular velocity is uniform for the whole wheel, and is the same as the angular velocity of the centre of gyration in these circumstances.

The centre of gyration bears a strong analogy to the centre of oscillation. It differs only in this, that whereas, in that case the operating forces are supposed to act at every point of the moving body, in this there is only one force acting upon one point.

It is found by the following rule:—Divide the moment of inertia of the rotating mass (the sum of the products of the weight of each point of it by the square of the perpendicular distance of that point from the axis of rotation) by the mass of the body, and extract the square root of the quotient. This will give the distance of the centre of gyration from the axis.

The centre of gyration of a straight line revolving round one of its extremities is at the distance $\sqrt{\frac{1}{3}}$ (i. e., 5.8) of the length of the line from that extremity.

The plane of a circle revolving about the diameter has its centre of gyration removed from the centre by one-half of the radius.

The distance of the centre of gyration from the axis of motion is always a mean proportional between that of the centres of gravity and oscillation. Any two of these, therefore, being given, the other may be determined.

Centre of Oscillation. If we conceive a set of points, such as A, B, C, connected by infinitely light though rigid rods with the point O, and allowed to vibrate as pendulums round that point, we shall have the several motions com-

encing with different velocities. Gravity tends to impress upon all bodies upon which it acts *freely*, equal velocities, and thus A, B, and C, if left to themselves, would fall through A D, B E, C F in the first second, these being all equal. Now, according to the proposition of the parallelogram of forces, we may consider these motions as each

originated by two forces instead of one—the first pair being such as to produce a motion of A G and A K respectively in the first second, A G being a continuation of A O, and K G, a rectangle, having the diameter A D. So the other forces could also be decomposed, giving two forces which may be represented by B H, B L, and C M, C N, (L H and M N being rectangles.) Now, of the two forces in each case, that which acts along A G is destroyed by the resistance of O, and A K alone is left free to remove A. Similarly B H and C M are destroyed, and B L and C N alone left to move the points B and C. Hence A, B, and C, instead of moving through A D, B E, and C F, in the first second will move through A K, B L, and C N respectively. It will be evident at once that, as we approach the vertical O P, the motion will grow less and less, and at O P, in fact, all the motion would be prevented by the resistance of O. If we imagine now the points A, B, C, to be rigidly connected, some of them must slacken and some quicken their motion. The point A will be retarded by the point C, which does not move so rapidly of itself, and the point C again will be pushed onwards by the point A. The body, however, does move, and with a certain velocity. We can suppose a point s, which would move with the same velocity, accompanying the body stroke for stroke, and if this point s were free, rotating along with the body and the point immediately beneath it upon the body marked, it would be found that the relative positions of s and of that point would not alter. If, again, any mass were attached there to the body, suppose a heavy ball compressed into a point, the motion of the body composed of A, B, C, &c., would go on just as before. The point s is called the centre of oscillation.

It is most readily found in any given case by the employment of the methods of the calculus; we shall not attempt to give these here. It is always farther from the point of suspension than the centre of gravity is, and always in the straight line joining these two points.

It is necessary to find it, in order to arrive at an exact means of reducing a compound pendulum to a simple one, to which latter many readily understood laws apply.

The centre of oscillation of a given body is found by letting the body come to rest, when we can draw a vertical line in which the centre of gravity must be found, and in which the centre of oscillation, therefore, also lies. To find, then, its length from the centre of suspension, we divide the *moment of inertia* (the sum of the products of the mass of each particle of the body by the square of its distance from the point of suspension) by the product of the mass of the body into the length of the line from the centre of gravity, to the point of suspension.

The centre of oscillation of a straight line or a cylinder suspended at one end, will be distant from that end by $\frac{2}{3}$ of its length, while the centre of gravity is distant $\frac{1}{2}$ of its length. The distance in an isosceles triangle of the point of suspension (the vertex) and the centre of oscillation will be $\frac{2}{3}$ of the length of the perpendicular from the vertex upon the base. The distance of the centre of gravity from that point will be $\frac{1}{3}$ of the length of that line.

Centre of Percussion is that point of a moving body at which the impetus of the body is supposed to be concentrated. If we imagine the body perfectly rigid and non-elastic, then when the centre of percussion strikes against an immovable obstacle, repose should be produced. If the body strike at any other point but the centre of percussion, there would be a sort of rotatory motion round the fixed point. The impetus of some of the points would, in fact, not be destroyed, and that of others would be not only destroyed, but an impetus in the other direction imparted.

If, again, the body move round an axis, as in the case of a body suspended from a point, and strike against the centre of percussion, there will be no strain upon the axis or the point of suspension. If it strike against any other point there will be a certain strain.

If, for example, a ball swinging round from a fixed point strike against an immovable point at its lower part, the velocity of the upper will not thereby be destroyed, but it will move onward as far as it can, until the rigidity of the body, and its connection with the point stop prevent it, and then it will pull at the point of suspension in order to continue its motion.

There is a different centre of percussion for each of these two cases. When the body is moving freely, and gravity therefore acting freely, whatever direction the body may be moving in,

CEN

the centre of percussion is the same as the centre of gravity. This supposes that there is no rotatory motion combined with the rectilinear motion of the body. In that case it is not acting freely. If there be none, then whatever force acts upon each particle of the body acts uniformly like that of gravity, and acts in a constant direction. Hence, according to the parallelogram of forces, the force compounded of gravity and the impelling forces will act uniformly also. If the body move round a point or an axis of suspension, the centre of percussion becomes the same point with the centre of oscillation, and is to be found in the same way.

It is necessary only to remark, that a moving body will strike the hardest blow upon the opposing obstacle at the centre of percussion. At that point there is no interior strain on the particles of the body, and none upon the point or axis of suspension, in which, part of the value of the moving force would be consumed. The whole force acts upon the obstacle. Thus, since the centre of oscillation of any straight uniform stick is at $\frac{1}{3}$ of its length from the point of suspension, the hardest blow with a stick, may be given by hitting an obstacle with it at that point.

Centre of Pressure. A fluid enclosed in a vessel exerts a certain amount of pressure against the sides. It is manifest that this will be less at any point than at one lower down, because the whole weight of the body immediately between the points presses on the side of the vessel at the lower in addition to the weight at the upper. The principle of the equality of pressures, essential in *HYDROSTATICS*, (q. v.) at once establishes this. We have therefore the simple problem of parallel forces to deal with. So many forces acting against the vertical side of a vessel in horizontal directions, it is required to know their resultant—if there be one capable of representing all of them—and its point of application. It is evident that, as the forces increase as we go downwards, the point of application will be nearer the bottom than the top, and, therefore, always lower than the centre of gravity. The value of the resultant forces will be the sum of all the pressures. It is not necessary, of course, that the sides of the vessel be horizontal.

The point is called the *centre of pressure* or *metacentre*. In the case of a vessel with a parallelogram for one side, the centre of pressure will be at the distance of one-third of the height from the bottom. In the case of a triangular vessel, whose base is at the bottom, it is one-fourth of the height only.

As the centre of pressure is the point of application of the resultant of all the pressures, a force applied in the opposite direction, and of the same amount, would neutralize these. This will suggest a practical method of determining centres of pressure.

Centrifugal Force. That by which a body moving about a centre has a tendency to re-

CET

cede from it. It is simply the force opposite to the tension of the string or the attraction towards the centre. See **CENTRAL FORCES**.

Centripetal Force. That by which a body revolving about a centre has a tendency to move towards it. Thus the tension of a string by which the revolving body is held, or the attraction resident in the centre and drawing the revolving body towards it, is the centripetal force. See **CENTRAL FORCES**.

Centrebaric. A word not much used now. It is intended to indicate the following principle: Every figure, generated by the motion of any line or surface, is equal to the product of the generating magnitude, by the length of path of the centre of gravity of the line or surface. This is merely a translation of the maxim that any body may be theoretically considered to have its mass concentrated in a heavy point, at its centre of gravity. In that case the figure generated by the body, would be measured by the length of the path of the centre of gravity, multiplied by the quantity contained in the body. In the original case, we have to consider, the different points of the body, as perhaps taking different paths. The centre of gravity is the point round which these differences compensate one another.

By aid of this principle, when the centre of gravity of a line or a surface is given, we can determine the content of the body or surface generated. When—as in a cylinder—the centre of gravity is readily inferred from the symmetry, this method of finding the content is very convenient.

The theorem is mathematically demonstrated by Guldinus, and goes by his name.

Cerberus. A small northern constellation near the hand of Hercules. It contains only four stars.

Ceres. One of the asteroids discerned first by Piazzi at Palermo, on January 1st, 1801. While looking for one of the stars of Lacaille's catalogue, he noticed a star beside the one he expected; and by next night this had changed its place, continuing to do so on the successive nights. He was interrupted, however, by sickness, and when he recovered, the planet had become invisible in consequence of its approach too near the sun. He communicated the discovery, therefore, and a number of observers having calculated the approximate orbit of the planet from his few observations, watched for its reappearance. De Zach, on the last day of that year, and Olbers, on the first day of the succeeding year, re-discovered the planet. It had been supposed to be a comet at the first. It looks like a star between the seventh and eighth magnitudes, and is therefore invisible to the naked eye. Its magnitude is less than that of our moon. For the elements, &c., see **ASTEROIDS**.

Cetus (The Sea Monster.) A constellation which received the names also of Pistrix and

CHA

Orphus. It is below Pisces and Aries, and is usually drawn with a fish's head, two paws in front, and a curled fish's tail. Its brightest star is called Menkar (α , Ceti), and is of the second magnitude. It is in the southern hemisphere.

Chains. For the principles of the equilibrium of Chains see ARCHES.

Chameleon. A southern constellation containing nine stars. It is situated on the colure of the equinoxes within the antarctic polar circle.

Chances, Doctrine of. A most important division alike of speculative and practical science. See PROBABILITIES.

Changes. See PERMUTATIONS.

Charge (Electrical). See BATTERY.

Charles's Wain, is a name given by some of the older astronomers to the constellation Ursa Major ($q. v.$) It was formerly called in England the "brood hen." Both the Romans and the Arabs called this constellation a wain or waggon.

Chart. A map of the sea, for the use of navigators, showing the relative positions of rocks, shoals, harbours, &c. See PROJECTION.

Chromatic. A series of sounds each one-half of a note distant from the other, is said to be arranged according to the *chromatic gamut* or *chromatic scale*. The name *chromatics* was applied by the ancients to that species of their music which divided each note into three lesser ones.

Chronograph. See CHRONOMETER.

Chronology. The science which treats of the divisions of time, arbitrary or otherwise. What we call arbitrary divisions, are such as date generally from some remarkable historical event. What we call non-arbitrary divisions are such as commence along with some marked phenomena in external nature. In fact, the one and the other are arbitrary; but the divisions of time into years, days, months, &c., being simultaneous with the period of complete evolution of a recurring phenomenon, are not of an arbitrary character. For the chief of these see BISSEXTILE, CALENDAR, YEAR, MONTH, CYCLE, &c. where the chief points of what is called *Mathematical Chronology* will be found. With historical chronology this work has, of course, nothing to do. See GRIFFIN'S *Cyclopædia of History*. See especially Ideler's *Mathematical and Technical Chronology*.

Chronometer: Clock: Chronograph. Instruments for the accurate measurement of time. They bear, to our command over this formal condition of all finite existence, the same relation as the telescope bears to our command of its other formal condition—*space*. The arrangements of the universe offer, as our most accessible unit of time, that grand and *invariable* apparent diurnal revolution of the heavens,—or, the *sidereal day*. The *index* or *hand* of a just chronometer should make one exact revolution during a *sidereal day*; and also indicate, by graduated parts of

CHR

that revolution, the requisite subdivisions of that day. In practice, this exact conformity of the revolution of the index with the duration of the *sidereal day* is not demanded; it is enough if the amount of the clock's daily *retard* or *advance* be known—(the clock's *rate*); and, if the observer may feel assured that his instrument will not *capriciously change that rate*:—that the graduation of the dial-plate, answer to the required subdivision of the day, is of course an absolute necessity. It will conduce to distinctness, if we arrange our remarks on the instruments employed for the above purpose under different heads.

(1.) *The Clock, commonly so called, or the Timepiece with Pendulum.*—The moving power of the modern clock, as is well known, is the *weight*: a cylinder is turned slowly round by the descent of a weight; and this slow motion, multiplied, and rendered apparent by aid of hands or indices, marks the progress of that descent. But such progress, although tolerably uniform, is quite inadequate to represent the flow of time with an absolute uniformity; nor was effective aid obtained from the old application of a *fly-wheel*, caused to alternate like the balance-wheel of a watch, by an obvious but rude artifice. The clock with weights did not become an instrument of Science, until Huyghens proposed to apply, as the supreme regulator of its motion,—the *pendulum*; whose laws had long before been discovered by Galileo. We owe to the great Florentine the two propositions;—that, provided the arc of oscillation be a small one, *pendulums of the same length oscillate in the same invariable period of time*; and that *the periods of the oscillation of pendulums of different lengths are as the square roots of their lengths*. Presuming, on the ground of these incontestable propositions, that the artist may obtain a pendulum whose oscillations shall mark, let us say, exactly *one second of time*; it is easy to follow the application of the fortunate idea of Huyghens. Imagine such a pendulum (not represented in the sketch) suspended from the pivot D, to which is also attached, by a short arm, the *anchor* or circular arc A B C. This anchor will necessarily oscillate, or move slightly, now to one side, now to the other, synchronously with the pendulum. (See woodcut on next page.) The wheel E—one of the main wheels of the clock—has that permanent tendency to move round which is impressed on all the machinery by the *weight*. When the pendulum is at rest however, the wheel cannot move, being then caught by the anchor; and it is only when the anchor is moved sideways that the wheel is momentarily set free. During each oscillation of the pendulum one tooth of the wheel escapes, so that the machinery of the clock, and of course its index, makes *one step forward*, or *one beat*, during one oscillation of the pendulum, or, as we have supposed, during *one second of time*. The mechanical adjustment of the wheel and anchor—termed the *escapement*—requires to be arranged

so that the machinery play well; but, whether it play easily or not, the simple attachment of the pendulum secures that the clock beat seconds. Starting in this way, with provision for the uniform indication of the *smallest* element of time,

Fig. 1.

an instrument so constructed cannot fail in representing accurately all the subdivisions of a sidereal day, by the graduation of its dial; and the entire revolution of its index will correspond with the exact sidereal day, provided the pendulum be of the *precise length* of a second's pendulum. No artist would pretend that he had secured a pendulum of this necessary length by the first act of construction; but he provides means for slightly lengthening or shortening that part of the instrument, as the practice or going of the clock may show that it requires; and, by employing these means, the observer easily and speedily can bring his clock within a very small daily rate of retard or advance,—say one or two-tenths of a second. One supposition alone remains—Is the observer assured that the clock, thus completed, will *keep its rate*, or that he may trust its indications, in circumstances which prevent his examining and determining that rate anew? In other and more direct terms, Is the observer assured that the length of the pendulum, once adjusted, may not be liable to capricious fluctuations? Unfortunately, the reverse is the case. All bodies expand under the influence of increasing heat, and contract on the advent of cold; and the pendulum rod is not an exception. On every change of surrounding temperature, therefore, the clock must alter its rate; and, as the quantity of that change is not exactly determinable otherwise than by subsequent observation, the clock would thus cease to be a permanently reliable measurer of

time. This defect might well have seemed fatal; but the ingenuity of the artist has overcome it, by an invaluable contrivance termed the *compensation pendulum*. The remedial artifice first suggested was the gridiron pendulum-rod—a composite rod of different metals, of different but known expansibilities. The suspension rod, G, it will be noticed, is attached—not to the ball, L—but to the cross rod, B B. Should G expand, the rod B B is of course carried *downwards*. Attached to B B are two rods, D D, whose tops are fixed to a cross rod C C, through the centre of which the rod G passes easily and *freely*. In case of expansion of the rods, D D, the cross bar, C C, is carried upwards. Fixed to C C, two bars, B B, stretch downwards, passing *freely* through the cross rod, B B, and carrying a third cross rod, A A, to which L is attached. These rods, B B, evidently expand *downwards*. The position of L, with regard to the suspension point of the pendulum, will in such a case be evidently affected, on an increase of temperature, by *three expansions*—two carrying it downwards, viz., those of the main rod, G, and of the rods B and B; and one carrying it upwards, viz., that of the rods D D. But if these three sets of rods—viz.,

Fig. 2.

G, B B, and D D—can be made of such metals, that the one expansion upwards accurately counteracts the two expansions downwards, the length of the pendulum will evidently not be affected, nor the duration of its oscillations altered, by any variation of temperature. The principle of compensation now described is perfect; and in practice it was eminently successful. Nevertheless, the complexity of the gridiron pendulum, and certain defects inseparable from that complexity, have caused it give way before another arrangement, so simple that it may be understood without the aid of a diagram. Suppose that instead of the weight L, the rod G carries a cylindrical glass vessel, nearly filled with mercury. When the rod expands downwards, the same variation of heat will cause the mercury to expand upwards, or *ascend* in the glass vessel, so that the practical problem simply is, to give such dimensions to the cylinder, and to place within it such a quantity of mercury, that this upward expansion exactly compensate or counteract the dynamical effects of the lengthening of the rod. It is not too much to say, that the mercurial pendulum,

as now constructed, leaves nothing to be desired; and a Clock governed by it, constructed by the best makers, may be received,—under correction of observations repeated as often as convenient—as a reliable and absolute measurer of Time

(2.) CHRONOMETERS, *commonly so called*; portable instruments; WATCHES.—The action of the Clock, as above described, depending on the undisturbed operation of gravity—alike in its moving cause the *Weight*, and its regulator the *Pendulum*—it is clearly requisite that the *repose* of the instrument be not disturbed. To do justice to a good Clock indeed, it is necessary to suspend it on a stone pillar, sheltered from the wind, but unconnected with the walls of any house, and not subjected to their tremor. But important purposes, alike in science and the arts, demand *portable chronometers*, faithful recorders of the lapse of time—capable, even while in action, of being conveyed from place to place;—instruments which must clearly depend on other agencies, alike for their *moving cause* and their *regulation*. The force of *gravity* is supplanted, in such chronometers, by the equally important and accessible mechanical force of *elasticity*. The moving power, or substitute for the Clock weight, is the force with which a strong spiral spring, *wound up* around an axle, uncoils itself; and, since the force of this uncoiling is not uniform, uniformity of motion is obtained from it by the tapering or pyramidal shape of the *fusee*—the name given to the wheel it turns. And similarly the office of the pendulum is performed by a *balance-wheel*, that oscillates regularly and isochronously, in obedience to the action and reaction of a spiral steel spring, delicate as a hair; one end of which is fastened upon its arm. The mechanism now described may be understood on a glance at the interior of a common watch. It is extremely fragile, in comparison with the comparatively solid and massive structure of the *Clock*; but, through the ingenuity and solicitude of the best artists, chronometers are produced that measure time with astonishing accuracy. The rate of these instruments is also liable to derangement through the influence of varying temperature; in consequence of its action on the balance-wheel. For instance, if *A B A B* be an arm, oscillating in obedience to any force whatever, around its centre, it will, through effect of a well-known principle of rotatory motion, oscillate slower if lengthened by expansion, and *vice versa*; so that, in the Chronometer, as in the Clock, increase of temperature will diminish the *rate*. Several modes of compensation have been proposed, but the following diagram illustrates the principle of them all. Let the arcs, *B C, B C*, on each of which is placed a weight *D*, form the circumference (an interrupted one) of the balance-wheel. Each arc is composed of two thin slips of different metals, lying side by side, the *outer slip* expanding somewhat more, under heat, than the *inner one*. When expansion takes place

then, it is easy to see that the arcs *B C* must become *more curved*, and that the weights *D* will be drawn thereby nearer the centre of motion—an approximation, on the part of the circumference of the balance-wheel, which is meant accu-

Fig. 2.

ately to compensate the recession of the motion of the arm, *A B*, through its being lengthened. It is due to our artists to state that the expected effect is here also to a considerable extent realized: but, the delicacy of the mechanism, should, if rightly estimated, render it in no wise wonderful that *compensation* is still the weak and fallible part of chronometers. Besides, the subject is of importance too profound, to permit that the inadequacy of prevalent methods be disguised. The emulation excited by the annual trials, and the publication of their results by the Observatory of Greenwich, has indeed succeeded in producing very large ameliorations; and, doubtless, when the highest care and skill are expended on them, instruments are constructed very nearly insensible to variations of temperature. But, unhappily, it is quite otherwise with the timepieces generally employed in our merchant service. The facts recently brought to light by Mr. Hartnup of Liverpool, surprise no one at all conversant with the actual state of these instruments. Five per cent. of them may very safely be pronounced utterly worthless—their rates varying with changes of temperature, so irregularly, that no *correction*, in the ordinary sense of the term, can be applied to them—the variations in question having no apparent law. But, even excluding these, it is the rarest thing possible to meet with an approximately good compensation. Generally speaking, for a change of temperature, from 40° to 60° , the mean average change of rate is *seven seconds a-day*: so that, however scrupulously his chronometer has been rated in harbour, a captain sailing from northern to southerly latitudes would, in eighteen days, mistake his reckoning of Greenwich time by nearly *two minutes*. Fortunately, the larger number of these instruments resume their old rate when the former temperature returns, so that their rate of variation is comparatively regular, and therefore calculable. Nevertheless, each chronometer *has its own special rate of variation*. It is incumbent, there-

fore, on every owner or master of a ship, to trust nothing, in existing circumstances, to a mere *harbour* rate. Before leaving port the chronometer should be tried under the influence of different temperatures, and the fact ascertained *whether its rate of variation has a law or not?* If it has not, the instrument is useless; if it has, the master ought to be in possession of that law, or of tables, that will enable him to correct for temperature. The loss of ships appears insufficient to remove the supineness of the merchant service, in this very simple but very important matter; and it would seem the duty of government to constrain attention to it. Nor is the precaution so necessary, beyond reach of any of our large seaports. Public observatories are now less uncommon; and the object sought for might always be obtained there. A mechanical remedy will doubtless gradually arrive, through still more improved modes of compensation.

(8.) The CHRONOGRAPH. An astronomical Clock beats seconds. But between one second and another some phenomenon may occur, and the observer requires to determine the fraction of the second at which it did occur. Hitherto he has done this by estimation. But, by an application something akin to the electric telegraph, a method is promised by which a second of time may be subdivided mechanically into hundredth parts, with almost perfect accuracy. Suppose a cylinder turning on its axis, and so governed in its rotation by the machinery of the Clock, that it will roll off, or deliver, say an inch length of a slip of paper in one second of time; the observer may, by a touch of his finger, cause a mark to be impressed on that inch of paper at the very moment of the occurrence of the phenomenon, and the position of that mark will indicate the exact instant of the occurrence. An apparatus of this sort has now been constructed at Greenwich. Mr. Airy has given a very detailed account of it in one of his recent annual reports. It seems complicated, but the ingenuity displayed throughout, is worthy of the mechanical genius of the Astronomer Royal. It answers perfectly, and will inaugurate a new era in observation, as far as the element of time is concerned.

Chronoscope. One of the very ingenious discoveries of the fertile Mr. Wheatstone. It is an instrument founded on the fact that luminous impressions on the eye *persist* for a certain time, or *endure* after the actual sensation is gone; and by which the discoverer, desires to prove the *instantaneousness* of certain luminous phenomena, such as the electric spark, or to measure their duration, however brief that may be. One mark suggested by Mr. Wheatstone is this:—The phenomenon is observed by reflexion in a mirror to which a rapid motion is communicated—a motion of such a nature, that supposing the luminous object *permanent*, its image would appear to describe a great circle. This accomplished,

it is clear that if the phenomenon be *instantaneous* its image will appear as a *mere point* of the circle, and will have no shape. If, on the contrary, the phenomenon have an *appreciable duration*, the image of it will stretch out and form an arc of the circle, greater or less in proportion to that duration; and the size of the arc will constitute a measure of that duration. An electric spark viewed in this way shows no elongation, so that we cannot attach to it any duration. The discontinuity of certain *flames* and other luminous streaks, have, in this same way, been rendered manifest to the eye. See VISION, LIGHT, VELOCITY OF, &c.

Cinematics. The science which treats of motions, without concerning itself, as Mechanics do, with their cause, and the physical ideas that are thus introduced. Suppose, for instance, that a given body moves with a certain rotatory and a certain advancing motion, it is the province of cinematics to trace out the complete path which every individual particle of the body will describe. The velocity of motion, and the forces causing it, may be of any magnitude whatever. Cinematics treats the problem quite independently. Cinematics forms, properly, an introduction to mechanics, as involving the mathematical principles which are to be applied to its data of forces. The distinction is very useful, but it has not, until recently, been clearly brought forward. M. Laboulaye (1849) has published the first treatise on the subject.

Circle. A curvilinear figure, whose definition is, that every point in the curve, or, as the curve is termed in this case, in the *circumference*, is at the same distance from a fixed point named the *centre*. The properties of the circle are well known, and are investigated in every treatise on Geometry. Speaking more generally, a circle is a curve of the *second order*, belonging to the class of the *Conic Sections*.

Circle, *Astronomical or Spherical*. A mathematical circle passing round the Heavens or some part in them. If the circle shall bisect the celestial sphere, it is called a *Great Circle* of the Sphere: such are the Equator, the Ecliptic, the Circles of Right Ascension, &c., &c. If it does not bisect the Sphere, it is called a *Small Circle* of the Sphere: such are all Circles of Declination (excluding the Equator), the Arctic and Antarctic Circles, &c., &c. The relations of three intersecting Great Circles of the Sphere constitute the subject of SPHERICAL TRIGONOMETRY.

Circle, in *Instrumental or Practical Astronomy*, signifies a *Circular Instrument* employed in the measurement of Angles: beyond question the instrument on the construction of which Mechanical Art has lavished its choicest efforts. We shall purposely describe this most important Element in an Observatory at considerable length; giving our reader notice that the principles now explained shall be accounted as understood by him, in all reference to smaller instruments

CIR

belonging either partially or mainly to the Circular Class. It were useless to occupy time in explaining how the angle between distant objects may be measured by help of graduated circular arcs; neither shall we refer to the time when *sights*, and not *telescopes*, were the guide of the observer, in his endeavours to fix the direction of any celestial or remote body. Previous to the application of those optical powers, by whose aid we now magnify spaces either distant or near, the observer could make no exact determination unless by aid of an apparatus of large size, and proportionally unmanageable. Doubtless, the illustrious Tycho, who has left us the picture of his great Quadrant, occupying the *side of a house*, would have rejected it as a fable, that posterity, by use of a circle, easily carried in a boy's hand, would be able to detect far smaller angular quantities than were perceptible to the whole apparatus of Uraniburg! Even after the application of the Telescope, angles continued to be measured by the Astronomer as well as the ordinary Surveyor, by *Quadrants*; a class of instruments of which we give a rude representation in the margin. The mode of applying a quadrant of this

21

Fig. 1.

sort will be sufficiently obvious on cursory inspection of the diagram. It is of more importance that the reader apprehend why the use of the mere *quadrant* was abandoned, and recourse had to entire circles graduated all round their rim. It is abundantly clear that, however accurate and fine the graduation of the arc of the quadrant, the action of the instrument could not be depended on, unless its entire structure and working involved no serious error. But who could answer for the perfect *cylindricity* of the pivot on which the Telescope turns, or who could answer for the

CIR

perfect *circularity* of the limb *ab*? No perfection of mere mechanical work could secure either of these requisites; so that the artist aimed, through a *change of form* of the apparatus, to insure that such error—apparently unavoidable—should be *compensated for*. And he accomplished this, by continuing the *quadrant* both ways, and converting the apparatus into a circle. The reader will now permit his thoughts to rest on such an instrument as below:—

Fig. 2.

Imagine, for sake of distinctness, that the division of the instrument can be read at the two ends of the Telescope, which may be supposed moveable around its pivot. If the pivot be not a perfect cylinder, or if there exist an error of *eccentricity*, its effect will be to jolt the telescope as it moves, from the centre of the circle. But it is plain that as the jolt, in whatever direction, will just bring one end of the telescope as much nearer the line of division as it removes the other from it, the *average* or *mean* of the *two opposite readings* will, in effect, correspond with the *one reading*, as it should be, were *eccentricity* null. Nor does it require that these readings be made at the ends of the telescope; they simply require to be made at the two ends of a diameter. In circles of this sort, the telescope is not detached, but clamped to the instrument. The instrument turns round *en masse*, and the reading is effected by fixed microscopes, one of which is represented attached to the stone pillar. Two such microscopes then, correct for *eccentricity*. And supposing the divided line not quite circular, the other great source of error above specified; supposing it *elliptical* more or less,—the reader will discern without difficulty, if he takes the trouble to draw an ellipse, and suppose its circumference

equally subdivided, that a reading by *four* optical microscopes must correct for error arising in any slight and unavoidable ellipticity. It has been the favourite plan of some artists to adopt four, eight; and three, six reading points to their circles. The ground of all compensation, however, is explained above. Ramsden was the first practically to comprehend the value of circular instruments, and two of his chief ones, placed at Palermo and Dublin, leave but little to be desired. Important modifications have been effected since his time, as will be seen below.—What we have further to say will be done best, if we separate these instruments into classes.

(1.) *The Mural Circle*.—The Mural Circle, the favourite achievement of the late Troughton, is represented in its leading features in the woodcut immediately preceding. The Telescope and Circle are closely attached, and they move round together on an axis sunk deep into the solid wall on whose face they lie. The division of the circle is on the side or edge of the limb of the circle and not on its face; so that the mode of reading is as the annexed woodcut shows. Troughton's mural circles

Fig. 3.

are usually from five to six feet in diameter. The one in the observatory at Cambridge exceeds these dimensions. They are meant to be so placed that their face, and the Telescope attached to it, sweep the meridian line. Their limb is divided usually to every five minutes of space; subdivision into seconds and tenths of seconds of space is effected by the *READING MICROSCOPES* (q.v.) The mural circle is necessarily of great weight; but to prevent that weight from bearing too hard on the pivot, a system of counter-balances was put in place, whose nature will appear more distinctly in the cuts given of the Transit Circle. This important instrument has only one function, viz.,

to determine the declinations or zenith distances of stars. It cannot, with requisite accuracy, give their right ascensions; on which account it is rapidly giving way, after having done much excellent work, to that other structure which we shall next briefly describe.

(2.) *The Transit Circle*.—Until quite recently, it was necessary to the right use of a *TRANSIT INSTRUMENT* (q.v.), that it be reversible; in other words, that the east end of its axis be turned to the west, and vice versa; and it is still of importance that such reversal be easily accomplished. Ramsden's circles were reversible, turning round on two pivots in the zenith and nadir; instead of being fixed to a wall like Troughton's; nevertheless, what they gained by their adaptability to the office of Transit Instruments, they lost through the absence of permanent fixture in the Meridian. The desideratum was supplied by Reichenbach of Munich. The instruments constructed by him are as fitted to give correct *transits*

Fig. 4.

or right ascensions, as declinations; and the form he adopted, improved at Munich by his successors Ertel & Son, and by Repsold of Hamburg, is rapidly becoming the normal one. The reader will readily understand the construction of the

Transit Circle on examining the two subjoined representations of the one placed by Ertel & Son in the Observatory of Glasgow. The first view of this instrument is a front one;—showing the telescope (see previous page) with all the attributes of a Transit Instrument, placed on two massive piers. When needful, this great telescope can be reversed with little trouble by aid of a subsidiary apparatus, represented in the cut, under article COLLIMATORS. By the Collimators, there described, the error of the telescope's collimation, as well as its steadiness in the meridian, can at all times be directly determined. Attached firmly to the ends of the axis of the transit telescope, are two perfectly similar circles of three French feet in diameter. One of these is meant to read minutes of space by aid of a vernier; its divisions are in silver, and to its rim the clamp is attached. The other circle is perfectly free; it is divided on a thin line of gold embedded within the metal of the rim, to two seconds of space, and to this line, four reading microscopes, capable of reaching tenths of seconds, are applied. The great mechanical fault of the construction, as now explained, is the place to

clamp of a heavy instrument ought never to be applied to the circumference of a comparatively slight circle. One characteristic of these foreign instruments is, the mode of fixing the reading microscopes. In the mural circle these were attached to the wall; not so with Reichenbach, Ertel, or Repsold. The foregoing side picture of the Glasgow Transit Circle may render the construction sufficiently plain. The view presented is that of the side of the Transit Circle on which the fine divisions lie. The inspection of these, and of their subdivisions, is accomplished by four microscopes fixed in the circumference of a smaller circle, represented in the cut, and named the *Alidade*. The axis of the transit telescope passes through the axis of the alidade; in fact, the latter coincides with the former. It may seem that instability is thus necessarily communicated to the positions of the reading microscopes, which assuredly ought to be absolutely fixed. The alidade, of course, does not turn with the telescope and its attached circles; although its fixity may be disturbed by effect of the eccentricity of the axis of the telescope which is revolving within it. Two effects may be impressed on the alidade by this eccentricity. It may, notwithstanding its clamp, be turned slightly round, or it may be subjected to a mere jolting motion, up and down or sideways. The latter is of course corrected by the readings of the opposite microscopes; and the former is corrected for, in every individual observation, by observation of a level attached to the alidade, which indicates and measures the minutest amount of displacement in rotation. The peculiarity of this apparently unstable mode of fixing the reading microscopes is this:—*They cannot change their place without leaving a record of that change on the level.* We deem it preferable to their establishment on stone pillars, for the same reasons that in the Barometer, a scale with known, although sensible rate of variation, is accounted better than one whose rate of variation is not known, and is definite although inconsiderable. There is no defect in the theory of these continental instruments. They are quite effective to fulfil their promise of enabling one observer to take at once the two co-ordinates of a star. The points in which they seem to fail—if any failure may justly be attached to them—is *stability*. The reproach of comparative fragility, or instability, has been frequently urged against continental workshops, as to all optical instruments. It is pleasant, therefore, to have to record, that the task of re-constructing a transit circle, has been not only undertaken but accomplished by the present eminent Astronomer-Royal, Mr. Airy. In complement of his unparalleled services to our great National Observatory, he has achieved the erection of a Transit Circle, consolidating the best conceptions of Reichenbach, Ertel, and Repsold; and superadding a degree of firmness neither contemplated nor attained by these

Fig. 1.

which the clamp is applied. The writer of the present notice, can very sensitively aver that the

erminent Artists. Mr. Airy's original conception (argued by his peculiar *dynamical* genius) was this:—To demand from Engineers, on behalf of Astronomical Instruments, that assurance of stability as well as accuracy, which they so readily supply elsewhere. The Astronomer-Royal must succeed. His new Transit Circle has very obvious advantages. The circles are closer to the centre of the Telescope; and there is no such thing as clamping at any circumference.

The foregoing brief account of Circular Instruments has left much unexplained. The reader must apply to larger treatises. But one point requires notice here. To read graduation aright the zero or beginning point of the order of degrees, must be fixed. The points usually endeavoured to be fixed, are the *horizontal* or the *zenith* points. The horizontal point is determinable in two ways. *First*; suppose a star is observed first directly, and secondly, by its image reflected in a basin of mercury; the line between, must be the horizontal line;—a mode of determining the line or point very common, if not universal, in good Observatories until recently. *Secondly*; take a *horizontal Collimator*, or a telescope whose horizontality can be assured by a *level*, and placed as to the main telescope in the position of the subsidiary instruments in cut under article COLLIMATOR. The horizontal point may be deter-

Fig. 6

mined thus, with all accuracy attributable to the *level*. But a more accurate process has superseded these; the process of observing the *nadir* point, or the point of 180° . As in the subjoined woodcut, the telescope is so placed over a trough of mercury, that by aid of a peculiar eye-piece, the observer can discern at once the threads of the eye-

piece directly, and the reflection or image thrown back from the mercurial level. When these coincide, below the eye, with the actual system of spider's threads, the Telescope must point to the Nadir.

(3) *Circle Repeating*.—It was at one time considered necessary that to obviate errors of division, every angle should be measured on different parts of the divided circle; and mechanical means were provided for effecting this. Circles of this sort were named *Repeating Circles*; but they are now in comparative disuse.

(4) *Circle Reflecting*.—A very important Nautical Instrument. See SEXTANT.

(5) There are innumerable other forms of Circular Instruments—*Great Circles*, *Universal Instruments*, *Prism Circles*, &c., &c., but the

principles on which these may all be judged, have either been explained or referred to; and we can attempt nothing more in this Dictionary.

See DIVISION, TRANSIT INSTRUMENT, READING MICROSCOPE, SEXTANT, VERNIER, &c.

Circular Magnetic Polarization. In the year 1845, Faraday published his great discovery of the action of magnetism upon light, and opened up an entirely new and interesting branch of physical science. His fundamental experiment is as follows:—A ray of light is plane polarized, say by reflection from a surface of glass. The state of the ray during the various conditions of the experiment is tested by a Nicol's prism. In the course of the polarized ray is placed a bar of *heavy glass*, or silico-borate of lead, which is one of the best substances for exhibiting the phenomena. The Nicol's prism shows, that the state of the light is not essentially affected by the transmission through the heavy glass. The ray is still polarized, and in the same plane as formerly. But a very different result is obtained in these circumstances, by the mere introduction of powerful magnetic forces. In the neighbourhood of the bar of glass, two powerful opposite electro-magnetic poles are placed near each other, and in such a position that the direction of the ray through the glass is very near the poles, and parallel to the straight line which joins them. Supposing now that the light passes through the bar of glass, and that the poles are not yet magnetized by the electric current. Let the Nicol's prism be placed in the position of complete extinction, so that none of the light is transmitted through it. If, in these circumstances, the force of the electro-magnet be developed by the passage of a current through its coils, the light immediately reappears through the prism, and this continues as long as the magnetic arrangement is sustained, and no longer. When the light has reappeared under the action of the magnet, it can be made to disappear by turning the Nicol's prism through a certain angle. The polarized light is essentially affected, therefore, by transmission through the *diamagnetic*; and the affection is found to be identical with that which we have described in CIRCULAR POLARIZATION, as produced under very different conditions. The light is still plane polarized, but the plane of polarization has deviated through a certain angle under the magnetic action. We may now give a brief statement of the known laws of this action of magnetism upon light.

We may, in the meantime, regard the silicated borate of lead as the transparent medium that manifests the action. In the fundamental experiment, as already described, the force employed was the electro-magnetic, so that the proper force of the electric current was modified. When the iron cores were withdrawn, the action of the current was still sensible, but very feeble, showing that the introduction of the magnetic body increases the intensity of the current's action

upon the ray, though it does not originate the action. Powerful effects are obtained by the employment of long helices without magnets, the transparent body being placed within the helix, and the ray being transmitted in a direction parallel to the axis. With regard to the direction of deviation of the plane of polarization, it is connected with the arrangement of the electric or magnetic forces, by a very simple law. If the ray is affected by the simple action of an electro-helix, within which the bar of heavy glass is placed, the ray rotates in the direction of the current. The action of the current, is to draw the plane of polarization with it, round the ray. If the action of the light be due to opposite electro-magnetic poles, we have only to conceive that the heavy glass is a magnetic body. According to Ampere's theory of magnetization, the surface of the heavy glass would be traversed, on this supposition, by electric currents in planes perpendicular to the lines of magnetic force. A plane polarized ray, transmitted through the glass within this *imaginary helix*, will rotate, as in the former case, in the direction of the current. If the electro-magnetic poles be reversed, the direction of rotation of the ray will therefore be reversed. It was stated, in the description of the fundamental experiment, that the direction of the ray through the glass was parallel to the line joining the poles. This condition is not absolutely necessary, but it is most favourable to the manifestation of the desired effect. Understanding by lines of magnetic force, those lines which are usually called magnetic curves, and which are represented in experiment by the arrangement of iron filings in the field of force, we observe generally that the rotation of a polarized ray, under magnetic action, depends essentially on the inclination of the ray to the lines of force in the transparent medium. If the ray is parallel to the lines of force, the effect is a maximum. As the ray deviates from this direction the effect diminishes, until the ray is perpendicular to the lines of force, when there is no result. The peculiar action that is now under consideration has been manifested by every transparent medium examined, except the gases and the most of the crystals. Faraday's heavy glass appears to be the best medium yet discovered. Pure silicates of lead have been found, indeed, which are twice as powerful, but they have the disadvantage of tarnishing rapidly in air. Every liquid that has been tried manifests the action to some extent. Among crystals, fluor spar, rock salt, and rock crystal, appear to exert a feebly sensible action, but the crystals as a class give no result. Many of these transparent media possess a natural rotatory power. In the case of such bodies, the magnetic is found to interfere with the atomic action, only in the way of simple super-position of effects, increasing the ultimate rotation of the ray when the direction of the current is favourable, and diminishing it in the same degree when

the direction is adverse. The amount of rotation of the ray, depends upon several elements. It depends, as we have seen, upon the nature of the transparent diamagnetic medium employed; it depends also on the quantity of the medium employed, or rather upon the ray-length in the medium, varying directly as this length, if other things are equal; it depends also upon the intensity of the electro-magnetic force, varying approximately, according to Faraday's statement, in the direct ratio of the intensity of the current. We learn, from the experiments of Bertin, that the amount of rotation of the ray is connected by a very simple law with the distance of the diamagnetic from the magnetic poles. When only one magnetic pole is employed as the circularly polarizing agent, the angle of rotation of the ray appears to decrease in geometrical progression, if the distance of the diamagnetic from the pole increases in arithmetical progression. When two helices are employed with opposite poles adjacent, their actions, estimated by the above law, are simply superposed. Two magnetic poles could not be expected to act in this way of mere superposition of separate effects, because of their powerful inductive action upon each other. The magnetic rotatory power appears, as already stated, to be a specific property of bodies. It is worthy of notice that this power depends, not only on the chemical and physical nature of the body itself, but upon the variable circumstances of pressure and temperature. Matteucci made the interesting discovery that a diamagnetic, submitted to pressure in a direction perpendicular to the ray, has its rotatory power modified, and this to such an extent—for example in crown glass—that the rotation of the ray under magnetic action may be entirely prevented. He discovered also, in heavy glass and flint glass, an increase of rotatory power by an elevation of temperature. With the same electro-magnetic forces, he found his specimen of heavy glass twice as powerful at the temperature of boiling oil as at common temperatures. Such are some of the more important facts which have been discovered in regard to the relations of magnetism and light. We shall only notice, in conclusion, an essential distinction between the Atomic and the Magnetic circularly polarizing actions—a distinction that may have occurred to the reader already. The former action does not depend upon the direction of the ray through the medium; it affects the ray with the same screw-motion, and to the same extent, for all directions, if the ray-length in the medium be constant. The latter action affects the ray most powerfully when passing through the medium in a particular direction, and not at all when in a perpendicular direction; and, for opposite directions of the ray, it does not affect the ray with the same screw-motion, but with the same absolute rotation. Hence, for example, if a ray be transmitted through a circularly polarizing medium, and be retransmitted by reflection

at the posterior surface, it will emerge in its original state, or with a double deviation, according as the circularly polarizing action is Atomic or Magnetic. On the theory of the Magnetic Rotatory Action little can be said. It is next to certain that the action is due to a peculiar arrangement of the molecules of the diamagnetic, but the nature of this arrangement is quite unknown. Faraday has suggested a state of tension, or a tendency to currents, in the diamagnetic, as the proximate cause of the phenomena. The history of a great discovery must be interesting in all cases, but more especially so, if the researches which led to it were founded upon a really philosophical and judicious expectation. In this view Faraday's discovery claims double admiration. He informs us that he had long been persuaded, in common with many other philosophers, that the various forms under which the forces of matter are made manifest have a common origin, and are in a manner convertible into each other. This persuasion extended to the powers of light, and led to many laborious but ineffectual researches, having for their object the discovery of the relations between electricity and light. Some of these investigations appear in the *Philosophical Transactions* as early as 1834. The fruitlessness of these researches could not remove the well-grounded persuasion referred to. He therefore resumed the inquiry "in a most strict and searching manner," and, after many ineffectual trials, succeeded at last, as we have seen. We may hope, after this, that the general conviction upon which he rested, in regard to the closeness of connection among the various natural forces, may yet lead philosophers to make similar exertions in other directions, and with similar or even greater results.

Circular Numbers. In arithmetic, numbers, all whose powers end in the same figure as they themselves do. Thus, any number ending in 0, 1, 5, 6, is a circular number.

Circular Polarization of Light. This is a subject that is full of interest, both to the experimental and the theoretical student of physical science. The facts connected with it constitute an important part of our present knowledge in optics; and the theory of these facts, which is due to the genius of Fresnel, is one of the finest examples of a clear, simple, and complete explanation of a varied and complex class of physical phenomena. The very difficulties that encompass the subject, in the present state of science, give an additional interest to it: we refer especially to the difficulties connected with the production of circular polarization.

Light may be circularly polarized by a very simple process. Fresnel's Rhomb, as it is commonly called, is a parallelepiped of glass, whose faces are inclined to each other at certain angles, dependent on the refractive power of the glass. If a beam of plane polarized light be incident upon one of the bases of the Rhomb perpendicu-

larly, so as to emerge at the opposite base after two internal reflections, the result is found to depend essentially upon the inclination of the plane of primitive polarization to the plane of internal reflection. When this angle is 0° , thus 0° or 90° , the emergent beam is plane polarized, as was the incident; when the angle has any other value, the beam is elliptically polarized; and particularly, when the angle is 45° , the emergent light is found to have undergone that peculiar change which is called Circular Polarization. Light, in the last of these conditions, has peculiar properties. First of all, it is destitute of every trace of plane polarization. When subjected to the action of any analyzer, such as a Nicol's Prism, it conducts itself precisely as common light. In this respect it differs most eminently from plane polarized light, which is extinguished in one position of the analyzer. It differs also from elliptically polarized light, the latter giving a beam of varying intensity for the different positions of the analyzer, though never extinguished. The property now mentioned might lead us to suppose that the action of the Rhomb, in circular polarization, is simply a depolarizing action, which reduces the plane polarized beam to the state of common light. We observe, therefore, that the properties of light in the state of Circular Polarization, distinguish it as clearly from common as from plane polarized light. One instance may be given in proof of this. If two beams, one of common light and the other circularly polarized, be subjected to the action of a Fresnel's Rhomb, the results are different in the two cases. In the first the emergent beam has no property, as far as we know, distinguishing it from the incident, or from common light in general; in the other case, when the incident beam is circularly polarized, the emergent is plane polarized. The state of circular polarization is therefore different from that of common light, since the two states are differently modified by one and the same action. We cannot enter into the details of this subject, but there is one point that claims our special notice, from the importance of its connections. It has been already stated that the action of the Rhomb upon a beam of plane polarized light depends on the inclination of the plane of original polarization to that of internal reflection. Let A denote this angle. We may speak of all its possible values as comprehended between 0 and 90° , including values properly negative, from 0 to -90° . If A has any other value than 0 or 90° , the light is, as we have stated, elliptically polarized, and if $A=45^\circ$, the elliptic polarization becomes circular. Let a second Rhomb be now placed, so as to receive the beam emergent from the first, and let its position be similar to that of the first; then the light emergent from the second will be plane polarized in every case—that is, for all the values of the angle A ; so that, by two internal reflections under proper conditions, we convert a plane polarized beam into one elliptically polar-

ized; and, by two additional reflections in the same plane, we reproduce the state of plane polarization. The finally emergent light, though plane polarized, is not in precisely the same condition as the original beam. The planes of polarization of the two beams are found to be different; they are inclined equally to the plane of internal reflection upon opposite sides of it; so that their mutual inclination is $2A$. By means of four internal reflections we can, therefore, make the plane of polarization deviate through any desired angle. In other words, a plane polarized ray may be made, by such means, to turn through any angle round its own axis. In connection with the preceding statements, we have now to refer to a very remarkable class of facts. If a homogeneous ray of plane polarized light be transmitted perpendicularly through a plate of rock crystal, whose faces are perpendicular to its axis, the ray after transmission is still plane polarized, but the plane of polarization has deviated through a certain angle. The result of transmission through the rock crystal is precisely the same as that of four internal reflections described above. This is the reason why the peculiar action of the rock crystal is usually described in connection with the subject of Circular Polarization. The laws of this action are simple, though the nature of it is not known. First, with regard to the direction of deviation. We may speak of the ray as propagated through the plate with a screw-motion; it is made to revolve, in fact, round its own axis while it is being transmitted through the crystal. In every particular crystal of quartz, the motion of the polarized ray is constantly that of a right-handed screw or of a left-handed, whatever be the position of the original plane of polarization, and whatever be the face of the plate upon which the ray is incident. In some specimens of rock crystal the rotation is to the right, in others to the left. This difference has been clearly connected by Haüy with a distinction in crystalline structure.

With regard, again, to the amount of the deviation, this depends upon the wave-length or the refrangibility of the homogeneous light transmitted, and upon the thickness of the plate. The angle of deviation varies in the direct proportion of the last of these elements for all plates or sets of plates derived from the same crystal. The most refrangible rays are deviated to the greatest extent in every case. Thus, in an experiment of Biot's, the deviations produced by the same plate $\frac{1}{8}$ of an inch in thickness, were 44° for the extreme violet of the spectrum, about 17° for the extreme red, and intermediate values for the rays of intermediate refrangibility. When a beam of white light has been plane polarized, and transmitted through a plate of quartz, the variously refrangible rays of which it is composed rotate unequally, as the last statement would lead us to expect. In such a case, a Nicol's prism will not extinguish the emergent light in any position,

but will give coloured images. Quartz is the only known solid that exerts the circularly-polarizing influence upon light transmitted through it without internal reflection. But there are many liquids that possess this property, such as oil of turpentine, oil of citron, and other essential oils, tartaric acid, syrup of sugar. What especially distinguishes this class of actions from that of rock crystal, already described, is the constancy of the results for all directions of the ray through the liquid. The rotation of the plane of polarization is as evident in the case of liquids as with a plate of quartz, but the rotatory power of liquids is much more feeble. Thus, concentrated syrup of sugar, the strongest of liquids in this respect, produces a deviation only $\frac{1}{10}$ of that due to a plate of quartz of the same thickness. We notice among liquids a distinction similar to that observed between different specimens of quartz, in regard to the direction of deviation. Some liquids, such as syrup of sugar and tartaric acid, make the plane of polarization turn from left to right; and others, such as gum arabic and essence of laurel, in the contrary direction. When liquids which possess the rotatory power are diluted or mixed in any proportions, there is a perfect preservation and superposition of effects. The same quantity of liquid, when traversed by a ray of polarized light, produces the same amount of rotation in all circumstances of dilution and mixture. We except from this rule the cases of mixture which are accompanied by chemical action. The peculiar action of transparent media that we have been considering has been very fully investigated by Biot. He has given to it the name of Circular Atomic Polarization.—The Theory of Circular Polarization may be now briefly referred to. According to the generally received form of the Wave Theory of Light, the molecular vibrations of a plane polarized ray are rectilinear, and constantly perpendicular to the plane of polarization. In a circularly polarized ray the vibrations are supposed to be circular, the planes of the circles being constantly perpendicular to the direction of the ray. If we suppose, then, that the particles in the course of a ray are arranged in succession in the form of a helix or screw-thread, and that the screw revolves round its own axis, without advancing, we have a representation of the movement of waves in a circularly polarized ray, according to the theory. There will be evidently two kinds of circularly polarized light, according as the screw in the illustration is right-handed or left-handed. The various properties of circularly polarized light are beautifully explained by this theory. We shall only indicate the explanation of the two distinguishing properties mentioned at the outset. The first is, the absence of all trace of plane polarization, though the circularly polarized beam is obtained from a plane polarized one by a very simple action—that of two internal reflections. To explain this property, we observe

CLA

that the action of an analyzer, such as Nicol's Prism, is to obstruct the passage only of those vibrations which are perpendicular to a particular plane, this plane holding a constant position in the analyzer, and revolving with it round the ray. Now, it is a property of the circular vibration that, if it be resolved into two rectilinear vibrations at right angles to each other, the amplitudes of the components are independent of their directions. A circularly polarized beam, when analyzed, will therefore lose the same quantity of light in all positions of the analyzer—that is—will present no sign of plane polarization. The second property mentioned was the convertibility of a circularly polarized beam into a plane polarized one, and *vice versa*, by two internal reflections at proper angles, in a transparent medium. In explanation of this property, it is proved very simply that a circular vibration is converted into a rectilinear one, if either of its rectangular components be accelerated or retarded by a quarter of a complete vibration; and that a rectilinear vibration is changed into a circular one of the same amplitude, by a similar acceleration of one of its equal rectangular components. We have only to assume, therefore, that in internal reflection there is an acceleration of those vibrations (say) that are in the plane of incidence, while those at right angles to this plane are not accelerated; and further, that the amount of acceleration due to two internal reflections at the angles of incidence proper to Fresnel's Rhomb, is a quarter of an undulation. This assumption is made, accordingly, as the basis of the theory of Fresnel's Rhomb, and more generally as a fundamental principle, in explanation of the mutual convertibility of plane and circularly polarized light by means of internal reflections. The assumption has certainly much in its favour. While upon the theory, we should not omit reference to the phenomena of Circular Atomic Polarization, which have been already described. The nature of the molecular actions that give rise to this class of phenomena is entirely unexplained. We may have a clear view of the difficulty, by supposing the incident beam of plane polarized light to be decomposed into two opposite circularly polarized beams; the action of the medium is then to be regarded simply as giving rise to an acceleration of one of the latter beams relatively to the other. Fresnel has proved, in the case of quartz, that two opposite circularly polarized rays traverse the medium with different velocities; but the difficulty is, especially in the case of liquids, to conceive an action, capable of producing such a result. See QUARTZ.

Clamp: The name of a portion of an instrument, whose function is that of arresting the instrument's motion. Applied to a railway carriage it is called a *break*.

The excellency of the clamp resides in two qualities. It must keep the parts of the instrument which do not require to be moved perfectly

CLE

still; and permit at the same time a perfectly unembarrassed motion to those parts which require to be moved. The clamp itself is sufficiently simple; consisting generally of two plates, connected by a screw, which can bring the plates to catch upon any object, and hold it close. The less of the object they so catch—if they hold it securely—the better; because the motion of the other parts will be so much the more free. A tangent screw is usually connected with the end of the clamp, and with the moveable parts; and is employed to produce very fine and slow motions.

Sometimes, instead of the clamp with two plates, a circular clamp is made use of; it is employed to hold a tube. It consists of a ring nearly fitting the tube, having a descending end as in the figure. The ring is made of elastic material, and when

the screw represented does not keep the slit quite close there is a sufficient opening out of the ring to let any body readily free. If the slit were the whole length of the mass, instead of being terminated as in the figure, it would not be easy to preserve such a clamp in good working order.

The best account of clamps, with a very full description of the various constructions, will be found in *Pearson's Practical Astronomy*, vol. ii. pp. 272-277.

Cleavage: A phenomenon presented by many of the slates and older stratified rocks which physical science has recently brought within its domain. The phenomenon is this:—Every one knows that a bed of stratified rock can generally be split with a certain ease in the direction of the strata; the housemaid who lays a block of coal properly on the fire bears unconscious testimony to this fact. But such old beds also split with comparative ease in some other direction, having no definite connection with the strata. This split is a cross split, and calls to mind the fact that crystals, such as Iceland spar, also split easily in two directions. The phenomenon in the case of the crystal attaches to the nature of crystallization; but this new direction of split, or this "plane of cleavage," which often runs uniformly through vast mountain masses, cannot be explained by the ordinary processes of crystallization: nor until quite recently did any rational theory or physical cause seem to the geologist to be attainable. Professor Sedgwick, indeed, had a considerable time ago, ventured on the conjecture that probably polar forces of some sort were developed amid the molecules of a stratified mass, after its stratification; and that—inasmuch as a bar of iron, after the lapse of years, shows a tendency to become crystalline—so may the solid rocks tend to a similar state;—whence these planes of cleavage. The idea was an imposing one, and has since been swollen to gigantic di-

mensions by the Norwegian Kellhan, in whose opinion even the crystalline granite masses are only stratified rocks metamorphosed by a tendency of such a kind, operating during immeasurable ages. Now that we have reached it, however, the true cause turns out vastly more simple. We owe the discovery and exposition, to Dr. Tyndall, of whose exceedingly interesting memoir Sir John Herschel has worthily said, that since reading, a great many years ago, Wells's little tract on *Dew*, he had not met with anything that seemed to bring so many loose-lying phenomena under a general and very simple principle. It would be wrong, however, to omit mention of Mr. Sorby. This very acute and promising geologist had clearly approached the truth; but unfortunately he appeared to consider that a subordinate portion of the phenomenon plays a principal part. Dr. Tyndall's theorem is this:—*Rocks distinguished by planes of cleavage, have been subject to enormous pressure or squeezing in a direction at right angles to those planes.* He shows by irrefragable evidence, *first*, that such pressure has existed, and, *secondly*, that it suffices for explanation of the phenomenon.—(1.) The fact that pressure of the kind supposed, actually occurred, is manifested by the contents of the rocks with cleavage. These rocks, for instance, contain organic remains—the relics of shells, trilobites, &c. Now those relics are universally squeezed up in the direction of the foregoing plane of pressure, that is, in a plane at right angles to the plane of cleavage. But the condition of inorganic constituents of the rocks give corresponding and equally emphatic indications. Most persons will recollect those yellow marks that so often appear in school slates. Those and similar ones, sometimes of considerable dimensions, found in the rocks, appear to have been originally deposits of very fine mud, in globular or almost globular cavities. Now the section of those masses in the direction at right angles to the direction of pressure, remains circular, but in the plane of pressure the section is elliptical, i. e., the globular masses have been pressed out into ellipsoids. In the same way—as Mr. Sorby has so well shown must be the case—the flat sides of all particles of mica, talc, &c., that are found in these rocks, lie in accordance with the cleavage planes, and therefore at right angles to the direction of pressure.—(2.) But while the reality of ancient pressure has thus been demonstrated, can that alone account for the existence of planes of cleavage? Rigorously defined lines of cleavage are merely lines of comparative weakness in the rock. Now the illustrations just adduced, show that all through the rocks subjected to such pressure there must be a plane of weakness situated exactly as above defined. It is clear that every compressible irregularity within the structure of the rock,—every discontinuous portion—every air-bubble, or water cavity, must be flattened and spread out in the direction at right

angles to the direction of pressure. Dr. Tyndall takes the homely illustration of “puff paste.” It is thoroughly to the point; for no cook can make “puff paste” well, unless, by pressure, the portions that will afterwards melt, are flattened and formed into thin cakes lying perpendicularly to the direction of the pressure. And thus, in the present, as in multitudes of other cases, the most puzzling and largest classes of phenomena, turn out, after all, nothing more mysterious, than operations unnoticed because familiar—passing hourly before our eyes! Dr. Tyndall refers to an illustrative experiment that must be felt as singularly conclusive. Taking a piece of wax, and using every means to make it as homogeneous as possible, he subjected it to pressure before his audience at the Royal Institution, and it came from the pressure with well marked planes of cleavage. And he used his theory most successfully to explain the exfoliating of railway bars and other analogous phenomena.—For instance, break a piece of ordinary iron, and you will discern that its structure is granular. If this mass be beat or pressed the granules are elongated; they yield and become plates. Hence exfoliation; the plates come off in leaves. In other words, the iron has got a *cleavage*.—Geology is thus not merely freed from an enigma; her inquirers may further conclude from the presence of slaty cleavage, that in former ages an enormous pressure, definite as to direction, must there have been at work.

Clepsydra or Water Clock. An instrument in which the efflux of water through a small orifice is taken as the measure of time. Two species of clepsydræ have been employed,—one wherein the fluid is allowed simply to pass through the orifice,—another where the level is constantly kept at the same height by the introduction of new water. The latter plan secures that the efflux of water be uniform. In the former case, it is clear that there is not the same weight of fluid pressing on that which issues at the orifice—when one-half (for example) has passed—as before. In consequence the velocity diminishes. If the water be pure, and the orifice very small, and quite clean, the law of efflux will be, that in $\frac{1}{m}$ th part of the time of the whole efflux, the amount of the water that shall have passed is $\frac{1}{m} \left(2 - \frac{1}{m} \right)$

Thus, in $\frac{1}{2}$ of the time, $\frac{3}{4}$ of the water will have passed; in $\frac{1}{3}$ of the time, $\frac{8}{9}$; in $\frac{1}{4}$, $\frac{15}{16}$; and so on.

It follows that the second method is the best for reckoning time. If we can keep the level constant, and at the same time not disturb the water, we shall evidently have a uniform flow of fluid, which may be measured by being received into a uniformly graduated tube.

The clepsydra is susceptible of very consider-

able mechanical refinement; and may become an instrument of great delicacy. It is supposed to have been in use among the Chaldeans. Scipio Nasica introduced it into Rome. Tycho Brahe employed it in his Observatory.

Climate. A word which, in its ordinary acceptation, signifies the general material relations of any country or district of the globe—to living beings within that region, or, more correctly perhaps, to Man. Climate, in this sense, comprehends, as Humboldt has said, “all those modifications of the atmosphere by which our organs are affected—such as temperature, humidity, variations of barometric pressure, its tranquillity or subjection to foreign winds, its purity or admixture with gaseous exhalations, and its ordinary transparency—that clearness of sky so important, through its influence, not only on the radiation of heat from the soil, the development of organic tissue and the ripening of fruits, but also on the outflow of the moral sentiments in the different zones.” To expiscate and declare the laws of the constitution of climate, under this wide acceptation of it, and to indicate the revolutions which actual climates have undergone, forms the object of one of the most extensive of the departments of existing physical research,—one that must build on all the physical sciences as a foundation, and draw also from history and ethnology,—a department properly termed *Climatology*.—To enable one to constitute or delineate the sphere of a distinct department of science, one requires to obtain, not a vague or general, but an exact definition of it; but this is precisely the thing that can never be obtained until a science, being nearly complete, has surveyed its own sphere and marked out its boundaries. At present, certainly no more definite initiatory definition can be given, than the one suggested by the foregoing extract, which is the essence of all the writings of Humboldt on this subject, viz: that climates ought to be considered identical or corresponding, which, in whatever latitudes or regions they may be found, offer the same or nearly the same conditions for the material well-being of Man.—Had our globe been a perfect sphere, and with a symmetrical distribution of land and water, the boundaries of climates would have been marked out by parallels of Latitude. But it is not so. And since differences of elevation; those contrasts which distinguish rigid matter from fluid, viz., the opacity, density, and cohesion of the particles of the former, in opposition to the transparency or permeability to light, and the mobility of the particles of fluids; the unequal distribution of vegetation, of still and running water, of winds and atmospheric currents; the diversity of the slopes or exposures of a country, as well as other minor circumstances;—all, may place countries of the same latitude under extremely various climatological conditions, it is very evident that mere

geographical place is but one element—and the simplest one—towards the exact determination of a climate. As a first step in the discrimination of terrestrial climates, Humboldt proposed that *parallels of Heat*, as well as of Latitude, should be drawn across the globe; viz., *isothermal* lines, or lines of equal mean heat during the whole year; *isothermal* lines, or lines of equal summer heat; and *isochimenal* lines, or lines of equal heat in winter. The idea thrown out by this venerable physicist has not lain dormant. And M. Dové of Berlin has recently enriched climatology by traces of lines indicating the equal mean temperature of the several months. The study of those lines may be said to constitute the basis of all actual climatology: and the following are a few general results. The progress of *isothermal* lines across the two continents, shows that the climates of Europe are of a lower mean temperature, than those, either of central Asia or of America; and that, in general, the northern hemisphere receives more heat from the sun than the southern. This difference begins to show itself in parallel of Latitude 20°, and goes on increasing towards either pole. Between lat. 0° and 60°, the difference is not less than 16° of Fahrenheit.—In the same hemisphere and under the same Latitude, the annual heat diminishes rapidly from west to east, in the interior of continents, while it follows the inverse course in countries near the sea coast. Between the two continents in the same hemisphere,—between the climates of the east and those of the west,—an opposition or contrast exists, resulting doubtless from the opposing influences of *continental*, and *liquid* or *diaphanous* masses. The influence now alluded to, is still more clearly marked, in the distribution of heat through the seasons. In America the summers are burning, the winters rigorous, and the intermediate seasons very variable, compared with those in Asia and Europe; and this contrast holds also for Europe and Asia. The *isochimenal* lines from west to east, in Europe and Asia, assimilate countries apart by 9° or 10° of latitude; and in the opposite way, the *isothermal* lines, bring together, localities separated geographically by at least ten degrees of latitude.—Such being the state of inquiry as to *Climatology*, and the mode in which alone it can be conducted,—this article closes. But there are other two important inquiries, viz.: I. As to the distribution of Climates as they exist; and, II. As to Climates as they have been.

Climates, Present Distribution of. The force principally determining the distribution of climates over the surface of the globe is, of course, the obvious geographical one. Geographical climate ought, indeed, to be considered the *genus*, whilst varieties under it are mere *species*. Each hemisphere may unquestionably be divided into vast zones, that in the main have a certain homogeneity in this respect. The cir-

cumstances modifying the effect of solar radiation, however numerous, have after all only a restricted action; they give rise to local dissimilarities, *individualizing*, so to speak, each special region, and affecting the regularity with which the solar influence diffuses itself from equator to pole: nevertheless, observations show that for every ten degrees of augmenting latitude, there are on the whole diminishing means, both of summer and winter heat. Placing one's self in the centre of such a geographical zone, and neglecting the divergences arising out of mere locality, one cannot fail to discern the action of grand cosmical and climatological influences,—for instance, the same types of vegetation and animal life, and the same conditions of health or sickness as regards Man. Under the line and near the pole, these phenomena reach their maximum of contrast: at an equal distance from these extreme points, the effects alluded to balance and sustain each other—each passing into its opposite and *vice versa*. It is thus, not unauthorized by nature, that a distribution, now very old, is still received, viz., that the globe can be parcelled out into *Regions of Cold Climates*, *Regions of Hot Climates*, and *Temperate or Intermediate Regions*. Of these three, we shall speak in some detail; merely noting at outset two definite facts or laws respecting irregularity of climate, or their difference in SPECIES. *First*. This series of *hot*, *temperate*, and *cold* climates, which one finds on passing from *Equator* to *Pole*, is reproduced in every geographical region, in connection with variation of *altitude* or *elevation* above the level of the sea. Mountains like the Himalaya, Chimborazo, Lebanon, St. Bernard, &c., present these different climates, superimposed, like the storeys of an old Edinburgh house: nay, the effect of elevation has been computed; and in the main it may be said that an elevation of two hundred feet, deteriorates a climate, as much as a displacement of the locality would do, from equator to pole, of one degree of Latitude. There are thus *climateric zones of ALTITUDE*, as well as *climateric zones of LATITUDE*; nor are the former less difficult to define exactly than the latter, depending as they do on soil, vegetation, exposure, &c. Nevertheless, *general laws* exist. (See those graphic maps by Humboldt, Berghaus, and Johnston.)—*Secondly*. Within each of these zones there are two secondary divisions, depending on the number and extent of the vicissitudes of the atmosphere. (1.) Regions in the neighbourhood of large masses of water, those namely on the sea-coast, or which are bathed by large Rivers, enjoy an atmosphere comparatively free from great changes; i. e., its temperature varies comparatively little, from morning till evening, from day to day, from month to month. On this account—mainly because of the neighbourhood of the sea—the equatorial zone from 0° to 15° lat., has a mean temperature no higher than 80°, except in the case of exceptional

localities like Senegal. For the same reason, plants may be cultivated on the coasts of England and Ireland, that cannot be found in the interior of continents of much lower Latitudes. The *lines* of corresponding vegetation, delineated on the fine maps already referred to, afford abundant illustration of the truth now spoken of. All such regions are peculiarly favourable to *horticulture*; even when the heats of summer are scarcely adequate to ripen the fruit, the cold is not intense enough to kill the tree in winter. (2.) In contrast with the foregoing are *continental climates*; distinguished by the multiplicity and extent of their meteorological variations. Just because they are far from the equalizing influence of the ocean, differences of temperature, of the moisture of the air, of barometric pressure, are strongly marked, between morning and night, from day to day, and month to month. These continental climates, for instance, our *Canadian* one, have, not unduly, been termed *excessive climates*, or rather *climates of excesses*.—We shall now characterize in as few words as possible, the *three* regular geographical climates.

(1.) *Hot or Torrid Climates*.—The sphere of this class of climates extends from the Equator to 30° or 35° of north and south latitude. It comprehends nearly the whole of Africa; all that great division of Asia lying to the south of a parallel from Syria to Tonquin, and passing through Lahore and Boutan; and the large portion of America, between California and the southern boundary of La Plata. The perpendicular radiation of the sun, accumulates, in equatorial climates, the maximum of heat; the mean of the year in the shade ranging from 80° to 85°, while that of summer reaches 90°. The tropical regions of the old world are considerably warmer than those of the new; and in either case the heat diminishes as latitude increases, very slowly indeed compared with its rate of diminution in the temperate zones. Transitions of temperature during the day are rare also under the torrid zone, and of slight comparative amount, seldom surpassing from 14° to 16°; the frequency and extent of these, are less in the new than in the old world; near the sea, than more inland; and generally in westerly than in easterly regions. In no part of the world is the diminution of heat through *elevation*, more felt than in the equatorial mountains; and it is not without astonishment that an European finds himself passing in a few hours from burning plains covered with the banana and the cocoa, to sterile regions buried under perpetual snows. Speaking generally, the heat of the equinoctial plains keeps between 65° and 100°; but between day and night their temperature sometimes varies by 36°, owing to the intensity of terrestrial radiation under skies so exquisitely serene. Barometric oscillations are much better marked in the tropics than in our temperate zones. The periods of the diurnal oscillation are 4A. 18m. and 9A.

3a. A.M. and 4a. 8a. and 10a. 28a. P.M., the difference between the maximum of the forenoon and the minimum of afternoon being very large. See **ATMOSPHERE**. Between the seasons of rain and those of arid heats, the intermediate periods are distinguished by extreme atmospheric perturbations. Autumn and spring, in the equatorial zone, resemble, in their meteorological versatility, the equinoctial periods of all countries; but they are of very short duration. The peculiar winds that influence the torrid zone further affect its climate: viz., the land and sea breezes, the monsoons, the trade-winds, the hurricanes of the Antilles, the tornadoes of the African coast, and the typhoons of the Eastern sea. See **WINDS**. This is not the place to speak of the effects of these tropic climates on vegetation and life.

(2.) *Frigid or Arctic Climates*.—These climates extend from lat. 55° , to the pole, and comprehend, in the north, Denmark, Sweden, Norway, Finland, Northern and Middle Russia, Siberia, Lapland, Iceland, Greenland, Kamtschatka, Spitzbergen, &c. The coldest point in the globe—now yet determined in the southern hemisphere—lies—in the north—at about ten degrees from the pole, north of Behring's Straits, and about east longitude 170° . The temperature of this point is $= -10^{\circ}$; that of the pole is about $+3^{\circ}$. Between latitudes 64° and 75° the mean temperature of spring is $+8^{\circ}$; that of autumn about $+10^{\circ}$; that of winter -22° ; and that of summer $+36^{\circ}$: results calculated by Foster, from the daily observations of Ross, Franklin, Parry, and Back. In these climates, spring announces itself by thin and flaky snow-storms, followed by plentiful rain and by westerly and southernly winds. Soon after, the ice breaks up, and masses of it detach themselves from the coasts; winds and currents tear them away, and a *debacle* takes place, in the midst of dense vapours that darken the atmosphere. The temperature rises from May to July, during which period there are few storms. The actual summer does not overpass this date. Its mean temperature is only 36° , and its extreme heat only reaches 60° ; the causes which enfeeble the usual benefits of summer, being the obliquity of the solar rays, the coldness of the winds blowing from the pole, and incessant evaporation. During the month of August, after some rain, the earliest snows fall; the thermometer descends rapidly; and in November the accumulations of ice in straits and passes, again oppose an insurmountable obstacle to navigation. Then begins winter, a season very rigorous without doubt, but which meteorologists have usually painted dark in excess. Between latitudes 70° and 78° the mean temperature of the year is not lower than between $+17^{\circ}$ and $+19^{\circ}$, although the extreme of cold reaches -70° . These terrible colds are felt in January and February, an epoch at which the polar winter is at its depth; then over sea and land, snow stretches far and wide;

glacial vapour disengages itself and mingles with the air; the sun, concealed below the horizon, reveals his existence by a mere twilight whose calorific effect is nil. The Aurora, by its magical illumination, somewhat supplies, indeed, the place of our luminary; but its brilliancy, unaccompanied by heat, in no wise mitigates the sharpness of the winter. Diurnal variations of the thermometer in these hyperborean climates do not amount to much; but the annual variations are very great. The changes of the barometer are quite in contrast with those affecting this instrument near the equator: beyond latitude 60° , the *periodical* variations disappear; while the *general* variations augment with the latitude. With the exception of the Aurora, there are no traces of electric phenomena in high latitudes. Winds blow there usually from north-east or south-west, suddenly veering from the one point to its opposite. In some localities, especially Spitzbergen, the southern winds are colder in winter than the northern ones. By the impulsion which the winds communicate to the air, they increase the sensation of cold—rapidly renewing the air in contact with our bodies; and by their irregularities, they frequently produce tempests that spread widely around. Rain is, of course, comparatively little known in the circumpolar zone; it falls in the form of snow or hail, highly crystalline in winter, somewhat softened and moistened in spring. The hail of such regions is simply frozen rain; and is not due to electric action, nor accompanied by electric phenomena. The general character of polar climates is necessarily determined by the duration and intensity of their winter. Beginning in October, it may be said to prolong itself into May; so that the other seasons run through their course in a few weeks: here summer is neutralized by nocturnal frosts and the lowness of its thermometric mean; spring and autumn, remarkable for a humidity that augments the persistent coldness of the air. Under the glacial zone, vegetation can scarcely be said to exist. Everything in the animal and vegetable world presents a dull, feeble, and monotonous aspect.

(3.) *Temperate or Intermediate Climates*.—These fortunate climates range from 30° or 35° to 55° north and south latitude. Almost the whole of Europe with its islands belongs to them; in Asia they embrace the fair and vast countries, stretching from the Euxine and the Mediterranean, to the empire of Japan and the great ocean on the south and east; the southern part of Africa is under their influence; and in America they include California, parts of Mexico and Canada, the United States, Chili, and Patagonia. The leading characteristics of the temperate zone are these. 1. The seasons are well marked; cold and heat alternate annually, each reaching its apogee, through a gradual transition from the other. Meteorological observations made in 26 stations, in the temperate zone, differing

in height and exposure, furnish as the annual mean temperature of winter, 26° ; of summer, 68° ; of spring, 62° ; and of autumn, 58° . 2. Although distinct, the seasons are very variable; while within equatorial and circumpolar regions, they are distinguished by a remarkable stability or evenness of temperature. 3. Those oscillations of temperature which are little perceptible from one day to another, in the other zones, are strongly felt in temperate climates from morning to evening, from week to week, month to month, and season to season. It is a rare thing that the thermometer remains at the same degree for five or six days at a time: within that interval it may indicate vicissitudes of 18° , 27° , or even 86° ; the scale of the entire variations is not less than 54° or even 72° , while at the equator, thermometric changes do not exceed 14° or 16° . The annual periods of chief versatilitv occur about the equinoxes. Near the vernal equinox, the mass of the atmosphere is agitated by gales blowing from all parts of the horizon, while both thermometer and barometer undergo sudden changes. The early portion of spring thus participates in the qualities of winter. Summer has three phases: the *first*, cold as the spring; the *second*, distinguished by a sustained elevation of temperature and dryness and purity of the sky; the *third* generally bringing with it electric disturbances, and leading in the autumnal equinox, marked like its predecessor by alternations of calm and storm, rain, fogs, and dew. In winter the atmosphere becomes steady and serene; rains succeed and alternate with snow; the sun is low in the sky, and the nights are long.—Such the features of the centre of the temperate zones; towards either extremity, they merge, of course, nearer to the climates of the equatorial or polar regions. It is in this zone that the influence of *locality* is the most sensible. According to the exposure of a place—according as masses of mountains shelter it—according to the neighbourhood of lakes, morasses, or sandy plains—its climate may be infinitely diversified; it may offer conditions totally different from those of surrounding localities, and rather analogous to what is found in countries more southern or northerly.

Climates, Ancient. The climates of various places of the earth were, at one time, quite different from what they now are,—probably of the whole earth. For instance, in coal fields in arctic regions, we have relics of what are now purely tropical plants. It is clearly enough indicated by geological research, that throughout those immense pre-historic, or rather, pre-Adamitic periods, there has been a succession of varying climates over the greater part of the terrestrial globe; and that the main feature of this change has been a diminution of heat, since early geological epochs. Various causes have been assigned for this remarkable change, to examine which fully, does not belong to a volume entering so

slightly into geological and cosmogonic discussion. It is necessary, however, to allude to them.

—1. The gradual alteration or *degradation* of the climates of the earth, has been attributed to the gradual cooling of the earth, or to the recession of what is called the central molten part of the earth's mass. It is not proved, however, that there is any such central molten mass, or that there has been this gradual cooling. Physical considerations are far from sustaining such an hypothesis: further, it is not consistent with certain astronomical phenomena, viz., the precession of the equinoxes: neither is it established that, from old epochs, there has been any, general, *gradual* degradation of climate.

—2. The hypothesis has been started, that the axis of the earth's rotation may have altered;—the present polar regions having been, through effect of such alteration, formerly equatorial ones, and *vice versa*. This hypothesis is not only gratuitous, but inconsistent with every known law. *The axis of the earth's rotation has never altered.*

—3. An explanation of a different kind has been proposed by Sir Charles Lyell. He attributes climate mainly to the distribution of land and water over the surface of the earth. And, since continents and oceans have often interchanged places, he conceives that regions, now arctic, may, on this ground, have been torrid. The cause is a *vera causa*, but not a *sufficient* one. It involves the fallacy of explaining differences of *genera*, by the causes of difference of *species*. No conceivable distribution of land and water could so far abrogate the efficiency of the Sun as to render possible, tropical plants in Melville's Island.—The difficulties involved in the problem are great, and certainly they are not overcome as yet.

Clouds. Respecting the formation and constitution of Clouds, much still remains to be investigated. In regard of constitution, the *Fog* and *Cloud* are identical: nor do they differ in anything save this; the *Fog* is a *Cloud* resting on the surface of the earth, while the *Cloud* is a *Fog* floating in the Atmosphere. Intending to advert especially to Inquiries concerning the origin of these *visible vapours*, under article FOG, we shall merely state here, that the formation in question is essentially distinguished from that of DEW, by the circumstance that while Dew falls or is precipitated, because the surface on which it falls is *colder* than the Atmosphere, Fogs rise and are diffused, because the surfaces from which they rise are *warmer* than the atmosphere. The formation or source of the former is the aqueous atmosphere itself; the source of the latter the moisture in the ground.—The *structure* of the particles or molecules of fog and cloud has been pretty closely examined; and the prevalent opinion is that they are not solid drops, but thin vesicles or air-bells, of the character of soap-bubbles; the collapse of which yields rain. The diameter of these vesicles varies *generally* with the monthly temperature;

reaching its minimum of about .0006 of an inch in August, and its maximum of about .0015 in December: the variation, however, is not regular, as another apparent minimum seems to occur in May. This vesicular constitution of the particles of clouds, might promise a solution of the puzzling question, why they float and even ascend; nor have conjectures been wanting that they may be filled with some light gas, after the manner of balloons. Chemical analysis has disproved all such hypotheses: and there is no need of them; for, on the application of known causes to the question, the difficulty will be found very nearly to disappear. In the first place, the velocity of the fall of such a vesicular particle, through the air, cannot be very great; just because, owing to the extreme tenuity of the aqueous envelope, the specific gravity of the particle can scarcely be appreciably greater than that of air. Secondly, a cloud that seems motionless, is often really falling. It must be recollected that the moment these vesicles come into contact with dry air, they dissolve and disappear; so that to a descending cloud, such a change as the following may frequently occur,—its lower part may continually be dissolving, while the upper is being continually increased by the addition of new vesicles. And, thirdly, an atmospheric force exists, directly opposed to the fall of clouds, viz., ascending currents. During fine weather the vesicle falls with a much less velocity than that of the ordinary ascending current; which therefore draws it upwards along with it. On this account cumuli are more elevated at midday than in the morning; towards evening, on the contrary, as the current becomes weaker the clouds descend and dissolve when they reach the warmer region of the atmosphere:—hence that remarkable transparency of the sky which often follows even a cloudy day. Horizontal currents also oppose the fall of clouds.—Referring again, as to the genesis of these vesicles, to article FOG, we shall proceed with an account of the Natural History of Clouds, and of their main functions.

(L) *Clouds, Forms of.*—A classification of Clouds according to their chief forms, was first proposed by the meteorologist Howard; and the one he gave, retains its place. He distinguished these masses into three main forms, the *cirrus*, the *cumulus*, and the *stratus*; to which he attached as subdivisions—the *cirro-cumulus*, *cirro-stratus*, *cumulo-stratus* and *nimbus*. The *cirrus* (the sailor's cat's tail) is composed of thin filaments, the association of which resembles sometimes a brush, at other times masses of woolly hair, and again, slender net-work. The prevalence of the *cirrus* constitutes the mackerel sky. The *cumulus* or summer cloud (the sailor's ball of cotton) appears as a large massive hemisphere resting on a horizontal base. Such hemispheres are often piled on each other, forming these great and gorgeous clouds that sometimes accumulate in the horizon, and present the aspect

of remote gigantic mountains crowned with snow. The *stratus* is a horizontal band, forming generally at sunset and disappearing at sunrise. Howard's subdivisions explain themselves; nor is any remark necessary here, except that the *cumulo-stratus* often assumes at the horizon a black or bluish tint; then passing into the *nimbus* or rain-cloud. The *nimbus* is distinguished by its uniform gray tint and its fringed edges; the clouds of which it is composed, are mingled so as to be indistinguishable. Of these various shapes of clouds, the *cirrus* and the *cumulus* are in all respects the most striking and important. After a period of continued fair weather, when the barometer begins to fall slowly, *cirri* are seen to appear, sometimes under the form of slender filaments, and on other occasions, as parallel bands arranged in obedience to some cause yet unknown, from South to North, or from South-west to North-east. Of all clouds the *cirri* are the most elevated, they are so high, that from the summits of the loftiest mountains their appearance is the same as when we look at them from the plains. *Halos* and *parhelia* are formed among the *cirri* exclusively; nor, if they are examined carefully by aid of a blackened mirror, does one almost ever fail to find amongst them, distinct traces of *halos*. But as these phenomena are due to the refraction of light by frozen particles, it would therefore seem likely that *cirri* are themselves composed of snowy flakes, floating in the atmosphere at a great height. The appearance of these clouds frequently precedes a change of weather. In summer, they announce rain; in winter, frost or snow. Even when the vane is turned towards the North, the *cirri* are often carried along by South or South-west winds, which soon descend and are felt at the surface. On the occurrence of that descent, the *cirri* become more and more dense, because the air is moister; they then pass into the *cirro-stratus*, and in a short time rain is precipitated. These same circumstances sometimes determine the formation of a light and wholly vesicular *cirro-cumulus*. This is the cloud which on passing before the sun or moon, causes these luminaries to be surrounded by *coronae*. The *cirro-cumulus* foretells heat. While the foregoing clouds are the produce in our northern zones of the South wind, the *Cumulus* owes its existence to ascending currents: its elevation is not nearly so great as that of the *cirrus*. *Cumuli* are characteristic of the finest days of summer; they appear in the horizon shortly after the sun has risen; their number and size increase till the hour of greatest heat; after which they diminish; and in the evening, the sky is again serene. They are formed as already hinted when ascending currents draw the vapours into the higher regions of the atmosphere; regions in which the cold air is rapidly saturated. If the current increases in force, the vapours and clouds become more elevated; and as they penetrate in this way into colder and colder regions, it occurs that the sky

—although fine in the morning—becomes quite clouded by twelve o'clock. Saussure has endeavoured to account for their rounded form by this mode of formation: it is undoubted that when one liquid traverses another, the former must, because of the reaction of the ambient medium and the mutual resistance of its parts, take on a cylindrical form with a circular section, or one composed of arcs of circles. Although *cumuli* generally disappear in the evening, they sometimes do not. In the latter case, they become, on the contrary, more numerous, their borders are less brilliant, their tint deeper, and they pass into the *cumulo-stratus*, especially if a stratum of *cirrus* happens to exist below them. This arises, because the higher and middle regions of the air are near the point of saturation; and rains and storms may then be expected.—See RAIN and HYGROMETRY.

(2.) *Clouds, Distribution and general Functions of.*—It were needless to endeavour to present any general view of the distribution of clouds over the whole surface of the Earth, inasmuch as the clearness or cloudiness of the sky is so largely influenced in every particular case by the nature of the soil—its power of absorption and radiation, its dryness or humidity. One grand fact, however, must be adverted to. Around the equator, and stretching a few degrees on each side of it, there is a vast *cloud-ring*, not precisely steadfast, but passing sometimes to the north, sometimes to the south—always existing, however, and nearly permanent as to its breadth. Almost all good voyagers have noticed it. The following extract from a log-book, by an American Captain, describes it as graphically as any. On entering the parallel 4° North Lat., Captain Sinclair writes:—"This is certainly one of the most unpleasant regions in our globe. A dense, close atmosphere, except for a few hours after a thunder-storm, during which time torrents of rain fell, when the air became a little refreshed; but a hot glaring sun soon heats it again, and, but for your awnings, and the little air put in circulation by the continued flapping of the ship's sails, it would be almost insufferable. No person who has not crossed this region can form an adequate idea of its unpleasant effects. You feel a degree of lassitude unconquerable, which nothing can dispel. After crossing the line I found that I had now surmounted all difficulties, and that the breeze continued to freshen and draw round to S.S.E., bringing with it a clear sky and most heavenly temperature—renovating and refreshing beyond description. Nothing was now to be seen but cheerful countenances, exchanged, as if by enchantment, for that sleepy sluggishness which had borne us all down for the last two weeks." The ring-cloud is coincident with the region or zone of Equatorial Calms; and something of the same sort distinguishes the calm-zones of the tropics of Cancer and Capricorn. Nor is it difficult to detect the physical cause of

that connection. The vapours that ascend in such masses, under the direct heat of the Sun, from the surface of the Earth in the Equatorial regions, condense into clouds in the upper atmospheric strata; and, as they are not swept away by winds, they hang over that belt of calms, and shield the Earth below it. Evaporation is thus to a large extent stopped, the Earth's surface protected from the torrid beams of the Sun, and the Equatorial zone rendered habitable. Precipitation, too, becomes not only possible, but plentiful; and underneath that cloud belt, we have the Equatorial Rains. From 5° South Lat. to 15° North Lat., the beneficial action of this cloud belt prevails; and its existence farther vastly modifies the meteorological habitudes of the more northern and more southern zones. But for the effects of these circles of calms, we should have had a really torrid or burnt-up equatorial zone on the one hand, and in the temperate regions perpetual precipitation or rains. Over all the Earth, too, we can trace effects of the clouds; not so striking, perhaps, but altogether similar. To view them as the mere sources of rain were wholly inadequate. They act still more remarkably in tempering the solar heat, and checking nocturnal radiation. A few cloudless days in summer, suffice to inform us how insupportable, anywhere out of the Polar Circles, were the direct heat of the Sun; and, even in summer, perpetual nocturnal radiation, under an unclouded sky, would change and deteriorate all our climates. Absence of cloud in it, and of course radiation unchecked, is one of those many considerations which induce us to suspect that our satellite, the Moon, has not yet reached those physical conditions which are consistent with the presence of organic life.

(3.) *Clouds, Electricity of.*—The question concerning the Electricity of Clouds, as well as that concerning the general Electricity of the Atmosphere, is still under keen debate. Of the conflicting opinions of Lamé, Becquerel, and Peltier, we shall here give those of Becquerel; meaning to refer pretty fully to the researches of Peltier under article FOG. When the sky is not clear, the electrometer sometimes indicates the presence of positive Electricity in the Atmosphere, sometimes that of negative; nay, if these indications be obtained by means of a kite, it is found that the electricity manifested, frequently changes its character, as the kite passes from one cloud to another. For instance, Peltier tells us that at one time, by means of a kite, he found the atmosphere *positive*, through the first zone of 60 yards; above that, of the thickness of 25 yards, lay a *negative* zone; while beyond that space, *positive* indications reappeared. It may be taken as universally true, indeed, that the clouds are in an electric state, only of less tension, than when storms are the consequence. And, because of this electric state, they are variously affected by the mountain masses that rise up amidst them.

To this cause, in all probability, must be referred effects observed among the Andes by Boussingault, viz., parasitic clouds of immense extent attaching themselves, so strongly to the *middle* portions of those vast trachytic domes, that the wind could not separate them,—lightning darting from this mass of vapours, and rain, mixed with hail, pouring down from them on the plains below. Let us reflect, however, on the causes of these different electric states. (1.) The *positive* electrification of clouds can be explained without difficulty. If a cloud is formed amidst a tranquil atmosphere, in its natural or positive electric state; it is clear that the same condition of electricity will characterize each of these vesicular globules,—the aqueous envelope of which must be regarded as a good conductor. When the electricity is feeble, and the vesicles considerably apart, nothing remarkable will follow, and the cloud will not pass into the condition of a storm-cloud; it will merely appear somewhat more highly electrified than the surrounding air, because it is a better conductor. If, however, the cloud is dense, and its globules close on each other, it may be regarded as a *continuous conductor*; and all the electricity of its interior, will, according to the laws of electric distribution, collect itself on the cloud's surface, where it will be retained by the pressure of the ambient air. A storm-cloud, thus formed, ought manifestly to contain as much electricity as the whole mass of air that furnished its vesicles; so that, however feeble the general atmospheric tension at the time, it is easy to see that, as the cloud occupies a large space, the electricity at its surface may acquire an enormous tension, and be prepared to take part in the stupendous action of a thunder-storm. Clouds formed in the ordinary state of the atmosphere must therefore be positively electrified, and will continue so if they remain at rest. Driven onwards by the wind, they lose their charge during their course, and cease to be storm-clouds. (2.) It is not so easy to apprehend the origin of the *negative* electricity of clouds. The most probable cause is this:—Rising directly from the ground, these Clouds transport upwards the *negative electricity of the Earth*. It is well known, for instance, that the aqueous mist arising at cascades is *negatively* electrified; as in the same way, the spray at the edge of any torrent. Now Saussure proved, by numerous experiments, that mists rising from the ground about sunrise, give precisely the same indications; and he concluded, generally, that all vapours formed on the globe's surface carry up a part—greater or less—of the negative electricity which the Earth usually possesses. It is not improbable, also, that clouds become charged negatively through effect of *influence* or *induction*. The Earth itself, for instance, sometimes becomes positively charged in this way, by agency of a cloud strongly electrified negatively; and there is no reason to believe that a dense cloud, of powerful positive

tension, may not act similarly by distant action on another cloud, either feebly electrified or not electrified at all, and in communication with the Earth. The positive electricity of the latter cloud would, in such a case, be driven off into the earth, and a negative charge developed in that portion of it nearest the former. Should communication with the Earth now be cut off, this cloud would continue in a negative state. The same kind of action, might bring about similar results, as follows:—The Earth always exercising a negative influence, and the Atmosphere a positive influence, on Clouds, any one of these floating near the Earth must be much more negatively inclined in its upper than in its inferior portions; but an increase of temperature might dissipate its lower strata, and in this case a cloud electrified purely negatively would remain.—From this mode of the formation, alike of positive and negative clouds, it may be inferred, as a general conclusion, that the condensation of vapours is always accompanied by an evolution of electricity, and that rain should, in all cases, manifest signs of it. (3.) Storm-clouds are found at all *elevations*. Rocks forming the culminating points of the loftiest mountains frequently bear marks of fusion and vitrification that can only be attributed to lightning. On one of the rocky pinnacles of Toluca, which project 15,000 feet above the level of the sea, Humboldt records that he noticed such effects; and Arago informs us, that clouds of high tension have been discovered, 26,650 feet above the low lands of the temperate zone. It is clear that they attain the highest elevations, since electric indications so frequently appear among the *cirri*, which, as we have seen, essentially belong to the regions of perpetual snow. Generally speaking, however, these clouds are comparatively low; the situation from which thunder proceeds, sinking to the distance of 5,000, or even 8,000 feet, from the plain. See THUNDER-STORM.

(4.) *Clouds, Colour of.*—The varied and evanescent colouring of the clouds—depending on the relation between light and those vesicles—has not yet been fully explained or even closely investigated. A few special remarks must suffice here. It is pretty evident that in all ordinary circumstances the *red* rays pass through those vesicles with greatest facility, and therefore in greatest abundance. Hence the fact, that when the air is filled with such molecules, the part of the sky below the sun is usually of a reddish hue—and that after sunset the region of twilight is of a deep carmine colour. In winter in our latitudes, this redness often prevails throughout the whole day; and in summer, when *cirri* are floating about, the same occurs several hours before the culmination of the sun. When, on the contrary, the sky, during day, is deep blue, the twilight presents a gorgeous yellow, or golden tint. The red colouring of the clouds is connected with a phenomenon often seen in moun-

tainous regions, called the rose-tint of the Alps. This occurs chiefly when *cumuli* or *cirro-cumuli* are floating in the west: the bare surfaces of the rocks then resemble masses of incandescent iron. The cause is, that reflected red rays are reaching the eye in greatest number, and these red rays strike on the rocks from which they are reflected, after passing through the atmosphere. See WEATHER.—Peltier would have us believe that clouds charged with negative electricity prefer the shades of slate-gray; while white, red, and orange coloured clouds are positively electrified—positions which as yet are certainly not established. But the whole subject remains in a crude state.—The reader is referred to instructive papers by Professor J. D. Forbes, in the *London and Edinburgh Philosophical Journal*.

Coffer-dam. A contrivance employed in the construction of bridges. It consists merely in a double row of piles filled up between with sand and earth, and surrounding the place where the piers are to be built. It is intended to prevent the disturbance of the work by the water.

Cohesion. All perceptible bodies are supposed to be made up of a very large number of smaller bodies or atoms, placed side by side. It is evident, however, at first sight, that though this supposition accounts for a body's mere existence, it does not account for the various phenomena resulting when force is applied to it. Suppose a piece of stone, of irregular shape, composed of a very large number of these atoms; when the force of gravity acts upon them, those not at the ground, or vertically above the particles at the ground, would fall, if the stone were made up of a mere aggregation of particles. Take a handful of sand and attempt to shape it like the stone. It is found to be impossible. Yet in this case, we have the atoms present as before, and they are placed near one another as before. Moisten the sand with some water, and the body may now be moulded. Why? Gravity will not now disintegrate the mass. For what reason?—Wherever no motion is produced, and when a certain force acts upon a body, one conclusion is inevitable, that a force equal in amount to the first, must be acting on the body in the opposite direction. Gravity produces no effect in this case, and there must therefore be a force acting opposite to gravity, holding up the particles of the body. If we apply a set of forces equal to those of gravity in the case of the dry sand, and in the contrary direction, we shall find that there is a similar equilibrium; and we infer from this a force equal to gravity, and in the line of its direction. Similar forces will be found acting in every direction, and they may bear any relation, according as the body differs, to the force of gravity. If the body be at any part broader than its base, then the forces we speak of must be more powerful than Gravity. It follows then that we have in certain bodies, forces binding their constituent particles one to another, preventing separ-

ation, and resisting separating forces applied in any direction. These forces are termed forces of *cohesion*.—In the case of which we have spoken, these forces acted between two different bodies. In that case their specific name is *adhesion*. See ADHESION. It is a kind of cohesion. We have no physical ground for supposing any difference in origin or nature, between the two kinds of forces. *Cohesion*, when employed as a specific name, is taken to signify the force which binds the particles of the same substance, one to the other. Thus, in the case of the stone, the forces which resist its disintegration, acting between the same kind of particles, are termed cohesive forces.—There are three principal conditions, under which bodies are found to exist. These are the solid, liquid, and gaseous. These states depend upon the relative amounts of the force of cohesion and the force of heat. The latter acts as a power repelling the particles of matter, one from the other. When, therefore, this force becomes greater in any case than the cohesive force, the body in question melts, and then volatilizes. In the solid state, the excess of the cohesive over the repulsive forces, is sufficient to counterbalance strains tending to disintegrate the body. In the liquid state, the cohesive and repulsive are considered equal; and hence the force of gravity is unbalanced, and liquids always sink to the lowest possible level. In the case of gases again, the force of heat is supposed to be greater than that of cohesion, and the particles of the body fly off, separating from one another with considerable repulsive force.—About the nature of the cohesive force, and the mode of its operation, nothing at all positive is known. One thing only appears, that it acts at insensible distances, and produces no effect in the majority of cases, until the particles upon which it acts, are brought within such distances. Probably there is a positive repulsive force acting before this, to which, when its results are most evident, we give the name of Elasticity. The whole subject is involved in much obscurity. See STRENGTH OF MATERIALS.

Cold is merely the absence or negation of heat. Disputes were for a long time prevalent as to which had a real existence, cold or heat, if not perhaps both. The acceptance of the theory, that heat is not matter, finally set the question at rest.

Collimation, Line of. A very important technical term, connected with the use of Instruments, in Practical Astronomy and Geodesy. In the field of view of a Telescope, there is generally a system of spider threads, placed, or meant to be placed, exactly in the focus of the object-glass and eye-piece. Viewed through the eye-piece, they present an appearance like that annexed, viz., a central vertical line, *A B*, with an equal number of others equidistant from each other, on

each side of it; and a central horizontal one, C D. Now, if line A B be exactly in the vertical *middle* or axis of the telescope, the instrument is said to be collimated vertically; and, in the same way, if C D be in the horizontal *middle* or axis of the field of view, the instrument is said to be correct as to *horizontal collimation*. But as neither the one nor the other adjustment is ever perfect, there are, in every telescope—when one aims at the last exactitude, an *Error of Collimation*, which must be allowed for in every observation. See CORREC-

TIONS. The direction and amount of this error are best detected by the use of the subsidiary instruments named COLLIMATORS.

Collimators, Vertical and Horizontal. Subsidiary telescopes, by whose aid, the vertical and horizontal collimation errors of great Astronomical Instruments, are now universally determined. Their nature and importance will appear by aid of the annexed cut, which gives a side view of the interior of the transit room in the Observatory of Glasgow. The central figure is

the large Transit circle of Ertel, already described; and one main object of the subsidiary instruments A B and C D, is to assure that its great telescope be vertically and horizontally collimated. The collimators are two telescopes of considerable size, placed horizontally on the tops of adjacent pillars, in the meridian line. It will be seen that they look into each other—*down each other's throats*—as the phrase goes, and that the main telescope can look into both. Suppose, in the first place, the main telescope removed or lifted up; each collimator can then see from its eye-piece, not only its own system of spider threads, but also the system or diaphragm in the focus of the other. It is manifestly easy in such a case to correct both vertical and horizontal collimation, but we say, of telescope A B; for if its diaphragm be brought into coincidence with the diaphragm of C D, a semi-revolution made in its wires, ought not, if there be no collimate error, to disturb that coincidence. If the coincidence does not hold after this semi-revolution, there is error in the position of the diaphragm of A B; and it must be moved, by the appropriate screws, until it shall be found to retain its place in reference to the diaphragm of C D, in both positions. Exactly in the same manner the diaphragm of C D may be corrected. This accomplished, and the central vertical wires or threads of the two diaphragms brought into absolute contact, the main telescope is replaced, and the observer looks through it, in succession, on the two diaphragms of the collimators. On looking down A B, the central vertical thread of the main telescope may be found either

to coincide with the central vertical wire of A B, or to be at a certain distance, let us say, *west* of it. If, on turning the telescope round, so that it looks down C D, its central thread be found, in the former case, coincident with the central thread of C D, or, in the latter case, at the same distance, *east* of it, there is no error of vertical collimation. But if these conditions are not fulfilled, an error exists, and must be either corrected mechanically by the screws or measured and allowed for. The Horizontal Collimation error of telescope may, by aid of these subsidiary ones, be also corrected; although this requires a reversal of the main Instrument, by the aid of the lifting machine.—To the Collimators, delicate Levels are attached, so that their deviation from absolute horizontality can readily be detected. These Collimators also enable the observer to dispense with the old and inconvenient arrangement of a remote *meridian mark*. Captain Kater was one of the earliest to propose the use of Collimators. One of his devices was, a vertical one—or a small telescope kept vertical, by resting, on a float in mercury. This is now dispensed with, chiefly through the extensive use of two horizontal Collimators, and of Bohnenberger's method of fixing the nadir point by reflection. See CIRCLE.

Colledien. A solution of the recently discovered substance, gun cotton, in ether, is so named. It is easily prepared, by immersing a greater or less quantity, according to the viscosity of the required solution, of common gun cotton in a mixture of one part of alcohol and two of sulphuric ether. From four to twelve

grains of cotton to the ounce of this mixture will give sufficient range of viscosity for most purposes. Collodion has chiefly, hitherto, been used in Medicine and Surgery, and in Photography. It forms an excellent covering and protection for wounds, more especially for parts from which the skin has been removed. It is in use in the dissecting-room as a protection, in the case of punctured or wounded hands, from the virus of the putrifying body. It also acts well in allaying pain in certain kinds of burns and scalds, and is useful as a styptic in arresting bleeding. In all these cases it acts, by the rapid evaporation of the solvent, leaving a continuous coating of cotton as a thin but air-tight covering, more closely and gently applied than could be effected by almost any other means. Its photographic uses are described under the head of—

Collodion Iodised. The iodide of silver, as is now well known, possesses the remarkable property of being rapidly decomposed by light, and, when arranged as a surface on which the image in the camera obscura is thrown, becomes the most valuable of all photographic agents. According to the method invented by Daguerre, and known by his name, the iodide of silver is formed at once as a thin dry film on the surface of a silver plate, by its exposure to the vapour of iodine. On account of the expense of silver plates, the very perishable and delicate nature of the picture, and the objectionable glare of the metal, it becomes desirable to obtain the sensitive coating on some other than a metallic surface. This Mr. Talbot and others have admirably accomplished on paper in the Calotype, for an account of which the reader is referred to the article CALOTYPE. There is, however, much difficulty in getting paper sufficiently uniform in its texture to produce negatives perfect enough, from which to print the pictures by the second part of the process. For this reason Sir John Herschel, several years ago, tried to spread the coating of iodide of silver on glass, but his success was only very limited, on account of the difficulty of getting a suitable medium wherewith to attach the coating to the glass, so as to enable it to be subjected to the processes of development and fixing. This was subsequently done, with great success, by the use of the albumen of eggs, and the results were most admirable. Certain difficulties of manipulation prevented the albumen process from becoming very general, more particularly as the substitution of collodion in its stead at once offered greater facilities—facilities, indeed, so great and important, as to constitute the basis for an extension of the photographic art to a degree formerly unthought of.

The purpose of this, necessarily short, article will be best served by first indicating a simple and effective mode of preparing the collodion—then of iodising it—subsequently relating the steps of executing the plate, developing the picture, and fixing; after which, some of the causes

which have been found, by the writer, to be the most common sources of failure in this delicate though simple operation, will be detailed. To prepare the cotton, take of strong sulphuric acid 60 parts, by measure, of nitric acid, 80 parts, of fuming nitric acid, 15 parts. Mix together, and immerse in it 12 grains of Swedish filter paper, or of fine cotton, to every measured quarter of an ounce of sulphuric acid in the mixture. Allow the paper or cotton to remain in the acid twenty minutes; then remove the cotton or paper by means of a glass rod, and wash well in five or six waters till all acid taste is removed; dry it in a heat little raised above that of the air. Care is to be taken that the fumes from the acids be avoided by the operator, as they irritate the lungs. —Let now one measure of alcohol be mixed with five of sulphuric ether, and add to each ounce four grains of the prepared cotton or paper, which, if it has been properly treated, ought to dissolve completely in a few minutes. It is now to be iodised as follows:—A saturated solution of iodide of potassium, in alcohol, is to be made and filtered, and added to the collodion in the proportion of two fluid drachms to each ounce of the collodion. The mixture may be used immediately; or, what is perhaps preferable, it may be allowed to stand for a day, to enable the sediment to subside; but it should not be forgotten that, day by day, it loses somewhat of its sensitiveness, and that, in the course of two or three weeks, it becomes nearly useless.—Supposing now that the glass plates have been cut to the size of the recess in the camera slide, they are to be rubbed over with and allowed to soak in a mixture of one part of nitric acid and six of water, and afterwards well washed in plain water, and dried with two or three successive bits of cotton, or still better, of linen cloth, until, when well breathed on, they show no signs of streaks or marks. The dust having been blown from the surface of the glass, the corner is to be held between the finger and thumb of the left hand, while the right holds the bottle and pours freely on the upper level surface a sufficient quantity of the iodised collodion. The plate is to be gently inclined from side to side, till the whole surface is covered, after which all that will run off is to be poured back from one corner into the bottle, taking care immediately to vary the direction of the vertical lines on the plate, to prevent the ridgy streaks which are apt to happen from the running collodion. From the very volatile nature of the ether, this process of coating the plate ought not to occupy more than a few seconds.

A few seconds more having elapsed, to allow of the partial drying of the film of exquisitely fine iodised paper, which has thus been spread on the plate, it is now to be immersed in the silver bath. For this part of the processes, as well as those which follow the exposure in the camera, darkness—except the somewhat distant light of a single candle—is necessary. The silver bath is

a solution, of the strength of thirty grains of crystallized nitrate of silver, to an ounce of water (distilled water being preferable), as much of the solution being used as to fill a gutta percha or crechary ware tray, somewhat bigger than the plate, to a depth of an eighth of an inch. One edge of the plate is made to rest on the bottom of the tray at one end, while the other edge rests in a small gutta percha hook held in the hand. It is then, steadily and without stopping or hesitation, allowed to descend on the surface of the silver solution in the bath, where it is to be left for half a minute, when it is to be steadily lifted up to its edge again for a few seconds, to allow of the evaporation of the ether; after which it is again lowered down for another half minute or so, and this repeated till the coating of iodide of silver appears flat, and perfectly free from all oily looking markings. It is now to be lifted from the bath, the drops of silver solution hanging to the border wiped away by blotting-paper, and it is ready for the camera slide. The time of exposure will depend on the strength of the light, and on the exposed aperture, and the length of focus of the lens. Experience alone can enable the operator to judge of this, periods of from one second to five or ten minutes being required for different circumstances.

The surface of the plate, when removed from the slide, shows no appearance of a picture; only an incipient reduction of the iodide to the state of metallic silver has taken place, and this must be further continued, by the application of what is called the developing or reducing solution. Two grains of crystallized pyro-gallic acid, dissolved in an ounce of water and ten drops of the silver—both added before using—forms an excellent developer. It is to be poured on, and, by a motion of the plate, quickly spread over the surface, when, almost immediately, the highest lights of the picture will appear as dark marks, and gradually the other parts will show themselves. When they are judged to have sufficiently come out, the plate is to be held under a stream of water and well washed, after which it may be taken to the light and fixed, by pouring over it a solution of cyanide of potassium, of the strength of twelve grains to an ounce of water. This quickly dissolves the unreduced coating of iodide of silver, and leaves only the pure silver forming the lights of the picture. The plate is then to be quickly and thoroughly washed in a stream of water, allowed to dry, and afterwards protected by passing over it a varnish, composed of amber dissolved in chloroform, or a saturated solution of gum damar in naphtha. Another developing solution is composed of eight grains of sulphate of iron dissolved in an ounce of water, and two drops of nitric acid added, and half a drachm of acetic acid, and half a drachm of alcohol. The use of the acetic acid and the alcohol being chiefly to enable the iron solution to flow freely over the surface of the plate, and thus to pre-

vent unequal actions giving rise to stains, a greater quantity can be added according to the necessities of the case.

If it is required that these pictures should be intense enough to print from—that is, if the lights must be sufficiently opaque to protect a piece of sensitive paper placed behind them from the light, so as to give a print of the picture—the exposure in the camera must be considerably prolonged; also, it is generally necessary to thicken the deposits on the plate, which may be done by first making a thoroughly saturated solution of corrosive sublimate in strong muriatic acid, mixing it with seven times its bulk of water, and pouring it over the plate while still moist after the washing from the cyanide solution, allowing the corrosive sublimate to remain on it till a dead whiteness spreads over the lights, then washing under a very gentle and small stream of water made to spread over the surface. Great care is now necessary, as the film is rendered exceedingly tender and liable to be torn. When it is thoroughly washed, a solution of five grains of iodide of potassium to an ounce of water, is to be poured out in sufficient quantity to cover it, or a saturated solution of hydrosulphuret of ammonia, which greatly increases the opacity of the film, and in the high lights renders it perfectly black, so as to answer the purposes of a negative in printing. It is now to be carefully washed, dried, and varnished, before being used for printing. The process of printing is the same as detailed in the article CALOTYPE. The usual causes of failure in the Collodion process are as follow:—Imperfectly cleaned glasses; hurrying the plate out of the silver bath before the greasy-looking marks have disappeared; want of speed and completeness in spreading on the developing solution; allowing the silver solution, which has run down and accumulated on the lower edge of the plate during the exposure in the camera, to run back on the plate before the developing solution has spread over it, thus preventing the equable development. If the collodion be pure and moderately new—the silver bath slightly acid, by the addition of a fraction of a drop of nitric acid, rather than alkaline—this beautiful process is most certain in its results.

Colours. This article is set apart for consideration of one of the most obscure and perplexing subjects in theoretical or speculative Optics, viz., the *colour of natural bodies*. But two remarks require, for the sake of distinctness, to be premised.—(1.) Decomposition of the solar ray by refraction, shows the white beam resolved into seven different simple beams or primary colours, viz.: the *violet, indigo, blue, green, yellow, orange, and red* rays. The reader will find all proposed analyses of the solar beam, discussed under SPECTRUM. Further, *light and colour* have for their efficient cause the vibrations more or less frequent—although

always inconceivably rapid—of an extremely subtle and extremely elastic fluid or ether; an ether whose density is evanescent, and its elasticity infinitely great. The different prismatic colours, regarded apart, result from undulations of the ethereal fluid, of different *lengths*. And colours are simple or composite, according as they originate in the superposition of identical or different undulatory movements. Compare LIGHT and UNDULATIONS. — (2.) A distinction must be made among what we term the colours of external objects: the phenomena of permanent colours which form the subject of this article, must not be confounded with colours that are accidental and variable. Of the latter class of colours, there are three chief sources, viz., *refraction* and *dispersion*, as in the case of the rainbow, the spectrum, cut diamond, &c.; *diffraction*, which bestows on the feathers of birds their exquisite shades, on the agate its brilliant reflection, and extracts from finely striated surfaces their magnificent net-work; and *interference*, to which are owing, in an infinite variety of ordinary circumstances, the production of the colours of *thin plates*. (Compare these articles.) The *permanent colour* of a body, on the other hand, seems to belong to the body itself. It is wholly independent of its shape, and appears as inseparable from its nature, as its density or any other essential physical attribute.—The doctrine set forth by Newton regarding the cause of the colour of natural bodies, is extremely artificial and defective. He considered it a case of what is now called *interference*; ranging it under the category of *thin plates* (*q.v.*): a theory which, under all its phases, as elaborately developed by M. Biot, has received a masterly refutation at the hands of Sir David Brewster. This latter philosopher, however, influenced probably by his early partialities towards the now almost abandoned doctrine of *emission*, (see LIGHT) appeared inclined to refer the phenomena in question to *absorption*, the designation of a department of optics which Sir David's long and fruitful labours have marvellously enriched. The notion that *absorption* is the cause of the permanent colour of bodies is still the common one; and, *in extenso*, it is as follows:—"A ray of light, which we have seen, is rather a *sheaf of rays* falling upon a body,—that body, because of its inherent qualities, takes in, or *absorbs*, a portion of the sheaf, and sends away or reflects the rest of it. But as the reflected portion alone meets the eye, and as that portion must be coloured, the eye attributes to the body the colour appertaining to that reflected portion." Since this proposed explanation assumes an occult cause or power, on the part of each body, to accept a part of the incident sheaf of rays, and to reject or reflect the other part,—it is clear that no supporter of it, is entitled to object to any other explanation, on the mere ground that peculiar and yet not-understood action on the part of the coloured body, is

assumed in it likewise.—The subject can be rightly entered on, in one way only. *Is the light which gives us the sensation of the colour of bodies, REFLECTED LIGHT?* And as all surfaces reflect light in so far, *can we separate the light they reflect, from the light which induces us to say that they are of such and such a colour?* Until these and similar questions are definitely answered, the doctrine of absorption can only be held as a re-statement, in difficult words, of the fact, that natural bodies are coloured. The classic memoir on one portion of this inquiry will always be that one of the remarkable *Œrsted*. Having shown first, that all bodies have, in a certain sense, the property of mirrors, he proves that their mirror-action has nothing whatever to do, in producing the sensation of colour which any body transmits. Whatever the nature of the surface, the *images* produced by it, and which are due to reflection, *have no colour*: or if a shade of colour tinges these images, that is owing entirely to the immediate proximity of the coloured body,—just as, in a room with green hangings, the complexion is affected. The light to which colour is owing, *Œrsted* considers due to, what he termed a decomposing reflection—something quite different from anything depending on more or less imperfect mirror-action. We are conducted onward an important step, by the researches of Benedict Prevost. This ingenious inquirer appears to establish, by no recon-dite process, that the phenomena of the colour of bodies is not due to any *reflection* of light, but to a *radiation*, so to speak, on the part of the bodies themselves: in other words, a substance on which light falls, does not accept one part of the sheaf, and reject the rest; it reflects the whole according to its ability, but the incidence of the ray originates a power in the body itself to become the source and centre of peculiar and therefore coloured undulations. Regular reflection could not produce, in regard to colour, any phenomenon not analogous to the *echo* in sound, which is heard only at a determinate point. But besides the echo, there is a *resonance* of the body itself, which is thrown into vibration by communication of motion—a resonance heard on all sides of it. The permanent colours of bodies are, according to Prevost, the result of a *luminous resonance*. Neither Prevost nor *Œrsted*, however, was able to bestow on these opinions that definiteness in which all satisfactory inquiry should terminate. *Numeri omnia regunt*. This was reserved for Arago. Partly by himself, partly by our own celebrated physicist, the laws of the *polarization of light* (see POLARIZATION) had long been established; and especially that essential difference pointed out, between *light polarized by REFLECTION* and *light polarized by REFRACTION*. Now Arago had for some time recognized, that between light arising from incandescent solids, and from gases, there is a wide separation. Light reaching us from incandescent solids is

polarized by refraction, proving that it emanates from the interior beds or strata of the solid body; while that reaching us from inflated gases is not polarized at all. On this ground, Arago established physically the correctness of Sir William Herschell's idea, that the light of the sun originates in a brilliant gaseous photosphere: but the same use of his polariscope has evolved results not less remarkable concerning the origin of the colours of natural bodies. If a sheaf of white rays falls on a polished white surface, the surface thus illuminated, sends to the eye, light in two entirely different conditions. Looked at under a certain angle, the light comes as if from a mirror; seen from any other point, the white light is dull, and as if dispersed. Now what is this dull and dispersed white light? Is it part of the ordinary beam, broken into shivers by the multitude of small irregular reflecting points on the surface of the body, or is its origin different? Of course, the main point to be ascertained was this—does that dull white light come from the surface, or from some interior portion of the white body? Now, when these two lights are analyzed by the polariscope, they are found to be oppositely polarized,—the former polarized by reflection, the latter by refraction, and therefore certainly arising from the interior of the coloured body. But what is the origin of this refracted mass of light? Is it portion of the incident ray, which, after penetrating to a certain distance within the mass of the body, then emerges; or, has it been evolved or generated within the body itself? The latter is the fact; and Arago thus demonstrates it. On illuminating a disc of white or opal glass, by a beam polarized in one special plane, he found that the body thus illuminated sent to his polariscope light polarized in the opposite plane. The light, therefore, which emanates from coloured bodies is not part of the light that falls upon them, but something generated within the bodies themselves. An ingenious experiment, lately reported by M. Botzenhart of Vienna, confirms these conclusions of Arago. By aid of the dichroscopic lens of Haidinger, Botzenhart separated the two images of the body—the one arising from ordinary reflection; the other being due to colour—the white image is always polarized in the plane of the incidence of the ray; the coloured image in the plane at right angles to it. Botzenhart, although in so far anticipated by Arago, infers the following propositions. (1.) The white light which illuminates bodies is reflected WHITE. (2.) The coloured light that reaches us from natural bodies does not come from their surfaces, but from their interior—having undergone an actual refraction. The second of these propositions had been previously established by Arago. The critical facts thus satisfactorily established, it remains to ascertain whether and how far they can be brought within the range of any of the accepted theories of light? Protected by

a certain reservation, we shall endeavour to express the amount of this apparent coincidence. The true author of the modern theory of colours is that great and comprehensive genius—Euler. It may be summarily expressed as follows. Since it is certain that any noise will make the chords of a harpeichord vibrate and emit a clear note; so the same thing may occur with reference to the objects of SIGHT. Coloured objects are like the strings of a harpeichord, and their different colours resemble those sounds, sometimes *grave*, sometimes *acute*. The light to which bodies are exposed is analogous to an external sound affecting a harp; and exactly as this sound acts upon the strings of the harp the light of an illuminated body may be supposed to act on the luminiferous medium *within* another body, and cause it to send forth its own, or *peculiar vibration*. As already confessed, an occult or not understood cause is presumed by this explanation, viz.: that the luminiferous ether within different bodies is in various conditions of tension,—conditions that render it most susceptible of a special kind of vibration within each separate body. But the force of the objection holds against every theory of natural colour; and this one has the advantage of quadrating with the exacter inquiries of CErsted, Prevost, and Arago. Still further: while light falls on a body and puts its ethereal molecules, or rather the ethereal medium within it, into vibration, the incident ray likewise is subjected to a sort of reaction on the part of the body which manifests itself under singular modifications. The primitive ray even when *white*, is not only, as if metamorphosed into a coloured ray; but this coloured ray becomes *discontinuous*—streaked by *dark bands*, at the points of its maximum and minimum intensities. The facts of this singular change were brought to light chiefly by Sir David Brewster, and will be noticed at length under FRAUENHOFER'S LINES. But it is to M. Ermann and Baron von Wrede that we owe the explanation of these, and their easy deduction from the foregoing theory of colour. The student who would go to the root of this subject is especially referred to a paper by the latter eminent inquirer, reproduced in *Taylor's Scientific Memoirs*. He will find there how all those dark bands, every shade of colour, and the most complete transparency or opacity, may be supposed to spring from one source—a special description of *interference*, or of retardation undergone by certain series of the undulations, propagated by bodies, when they originate the appearances of which we have now been treating.

COLOURS, ACCIDENTAL OR SUBJECTIVE. An extensive class of relations in which the observer stands to the phenomena of colour, because of peculiarities in, or re-action of, the visual organ. On several of these, remarks will be found under DALTONISM, EYE, IRRADIATION. At present we shall notice the phenomena of acci-

dental colours properly so called, or those purely subjective sensations of colour, which the contemplation of actually coloured bodies often brings along with it. There are two chief classes of these. (1.) *Sensations FOLLOWING on the steady contemplation of coloured objects.* Place a coloured object on a black ground, and look at it attentively. Its colour soon begins to fade gradually. Then turn the eye suddenly to a sheet of white paper: immediately an image of the object will appear, of the colour complementary to that of the original object. In other words the contemplation of a red object will give rise to a green image; a white object has a black image; a yellow or blue one, a violet or orange image; and vice versa. All such images remain visible for some time; both their intensity and duration depending on the length of time during which the eye was fixed on the object itself. The exact laws of the phenomenon are as follow:—As soon as the retina ceases to be excited directly by the coloured object, there occurs—*first*, the persistence for a very short time, of the primitive impression; *secondly*, the apparition of the accidental image; and *thirdly*, successive appearances and disappearances, more or less numerous, of the accidental image; and, in certain cases, alternating apparitions of the primitive impression and of the accidental image. (2.) The second class of accidental or subjective colours may be termed the *simultaneous* class. The appearances just referred to consist of images succeeding the contemplation of coloured objects; but experience proves that, even during that contemplation, there is another curious order of phenomena, also manifesting complementary colours. It was remarked by Buffon, for instance, that if one looks long on a coloured object placed on a white ground, colours rapidly develop themselves around the edges of the object, of the same shade as the accidental image already spoken of. Rumford showed, too, that if a shadow is produced within coloured light, the colour of the shadow is complementary to that of the light; that is to say, if a sheet of paper be illuminated by a green light, a body illuminated by white light, and interposed between the paper and the source of the green light, will cast on the paper a red shadow. Other curious similar phenomena have been noticed by various observers. The general law of these simultaneous subjective colours is as follows:—When we look, directly or indirectly, at a coloured space, there is developed around the edges of that space a considerable breadth of the complementary colour, of greater or less intensity; which intensity, however, gradually diminishes as its distance from the object diminishes. (Black and white, in all these cases, rank as complementary colours.) And if two coloured spaces or objects are near each other, they seem to have a reciprocal action; regard being had to the size and brightness of each. Minute details may thus be summed up:

At a distance from the edge of the coloured object we find—*first*, a slight prolongation of the actual impression; *secondly*, beyond this prolongation, extending to a considerable distance, the development of the accidental colour; and *thirdly*, in certain circumstances, beyond the space occupied by the accidental colour, a new development of the actual colour of the object.—The explanation generally adopted, regarding the first class of phenomena, is that of M. Scherffer. It presumes that the continued action of rays of a certain colour, on the retina, enfeebles its sensibility to these rays; so that, on the eye being directed to a white surface, the part of the retina affected, receives an impression from the other rays only, or from the complementary part of the white beam. M. Plateau, in an exceedingly interesting memoir, has attempted to refer both classes to the same physiological principle. According to him, the *persistence* of the primitive impression, as well as the *accidental colours* of the *first class*, constitute the transition of a portion of the retina from an excited to its normal state, the transition being considered in reference to the time required to accomplish it; while *irradiation*, and accidental colours of the *second class*, constitute or mark the same transition, as taking place in space—the transition between the actually excited portion of the retina and that which is in repose.

COLOURS, Complementary.—If two colours make up white when they are mixed, the one is said to be *complementary* to the other. Black and white, light and darkness, are also held as mutually complementary.

Columba Neechi. A southern constellation,—one of those named in modern times. It has no stars above the third magnitude.

Colures. Two great circles of the Sphere, or rather, two pairs of semicircles. If a great circle be supposed to pass through the pole of the Earth and the pole of the Ecliptic, it will pass also through the points at which the Sun has the greatest North and South Declination: the halves of this great circle—the one passing through the tropic of Cancer, the other through the tropic of Capricorn—are the *Solstitial Colures*. The other great circle passes through the equinoctial points; and its halves are the equinoctial colures.

Coma Berenices (Hair of Berenice), a constellation in the northern hemisphere. It is not one of the more ancient, possessing no large stars. Tycho first gave it a distinct place in the sky.

Combinations. See PERMUTATIONS and PROBABILITIES.

Combustion. See HEAT.

Comets. An extraordinary class of cosmical meteors, some of which are at present connected with our planetary system; the greater number being known to us only because they traverse that portion of space within which our system lies. A Comet, as it usually appears, consists

COM

of a nucleus more or less bright, environed by a nebulous atmosphere or *chevelure*, and attended by a still fainter nebulosity or *tail*, stretching out linearly, often through an immense distance. The nucleus or the *head* of the Comet, notwithstanding its aspect of comparative solidity, is itself altogether nebulous; for the telescope dissipates every trace of a solid mass, and clusters of small stars, which even a cloud would have obscured, have been seen through the heart of it. The shapes of these singular meteors do not, however, always conform to the foregoing type. At times they appear with several tails; in some cases there is no tail properly so called, only the nucleus is not quite symmetrically placed within the chevelure; and in other instances they present a mere nebulosity, with no trace of a nucleus. It is unnecessary to remark how strongly these bodies are contrasted with the organized planets of our system. Neither is it astonishing that their unwonted aspects and unexpected apparition, caused them to occupy, for many centuries, the place of *portents*. Science has now dissipated all such delusions; and, although much concerning the physical constitution of Comets continues unknown, we already have recognized their subjection to certain great and definite Laws of the Universe; and can welcome them, besides, as instruments likely to enable us to attack successfully certain momentous cosmical problems that could not be reached without them. We shall arrange what we have to say in detail regarding Comets under three distinct heads:—

(I.) *Comets, Motions, Periods, and Numbers of.*—It is now thoroughly established that, erratic though these singular bodies appear, they are, in all their motions—in the neighbourhood of our Solar System, at least—governed by that same law of gravitation which controls the planets as they revolve around the Sun. Newton's signal discovery—that a body obeying this law might move either in an ellipse of whatever eccentricity, or in any other conic section—doubtless awakened in the mind of his devoted follower, Dr. Halley, that *a priori* suspicion, which resulted in the famous prediction, that the Comet, rightly bearing his name, would be found to revolve around the Sun, in an ellipse, in a period of 75 or 76 years. Apart from his conviction of the reality of that principle of Order, which his illustrious friend and teacher had detected amid the great, actual, and the still greater, possible, variety of planetary motions, Halley would scarcely have ventured to infer—even from the striking correspondence of earlier records with the phenomena he saw—that the capricious meteor under his own inspection, and those which had arrested former observers, were one and the same: certainly he would not have hazarded the prophecy that, after the lapse of another 75 or 76 years, this Comet would return. The year in which this body appeared to Halley and

COM

his contemporaries was 1682. Flamsteed conjoined to his other eminent services, that of carefully determining the Comet's places; and it was the remarkable correspondence of *parabolic* elements, as afforded by these places, with the similar elements of the meteors that distinguished the years 1581 and 1607, which led Halley to the conclusion that "the Comets of those three years—viz., 1531, 1607, and 1682—are one and the same Comet, that had made three revolutions in its elliptical orbit." Taking certain disturbing effects, on the part of the planet Jupiter, into account, he concluded that the Comet's next return to its perihelion might be delayed until the beginning of 1759; and, in advising the astronomers of that day carefully to look for such re-appearance, he expressed a hope, which certainly has not been disappointed, that, in event of its return, posterity would not refuse to acknowledge that its periodicity had first been discovered by an Englishman. As the year 1759 approached, astronomers became more and more alive to the consummate importance of Halley's prediction; and those very laborious computations, rendered necessary by the comparatively advanced state of physical astronomy, were undertaken and brought to a brilliant conclusion by the celebrated Clairaut, assisted by Lalande and Madame Lepaute. The nature of the indispensable computations will be best understood, with the orbit of the Comet before us. This is represented in the annexed diagram.

The contrast between this cometic orbit, and the paths of the planets, need scarcely be pointed out. The paths of the latter are far apart from each other; and, notwithstanding their eccentricities, they never intersect; nor do the bodies moving in them, come at any time very near each other: hence, the reciprocal influences of these orbs are comparatively small—impressing only slight changes on the shapes of their orbits, or their periods. But the path of Halley's Comet is such that, in the course of a revolution, it may, through great proximity to some planet or planets, be seriously affected as to its course and period; so that an exact estimate of the planetary perturbations, is essential to any just deter-

mination of the date of its return. In Clairaut's time, unfortunately, these perturbations could not be minutely estimated, since the masses of Jupiter and Saturn were not exactly known, nor had Uranus or Neptune been discovered. Clairaut did not pretend to an ultimate exactitude; for, when hazarding his first statement—that the Comet should be found at its perihelion on 13th April, 1759—he confessed that he might be in error a full month. *The Comet came to its perihelion on 12th March.* This approximation was wonderful enough; more than adequate to establish the reality of the sway of gravitation over these wandering meteors. But when another period of 75 years had completed its course, Science had to reach still greater triumphs. Halley's Comet reappeared at the close of 1835. The masses of Saturn and Jupiter were now determined, and the influence of Uranus could be taken into account. The investigation was of course renewed. It was best performed by Rosenberger of Halle; and the occurrence agreed with the prediction, within *five days*—surely a trifling discrepancy considering the long period of that mist's revolution! Since then, Neptune has been revealed; and when this comet again returns, it is not likely that the error of calculation may exceed as many hours! It is indeed a matter of no slight gratification to the Human Intellect, that amid all external obstructions, and its proper imperfections, it can yet ascend so closely to the seat of Nature's most intricate laws! The actual dimensions of the orbit of Halley's Comet, as determined by the late Hermann Westphalen, are as follow:—

Least distance from the Sun,	55,900,000 miles.
Greatest distance,	3,370,300,000 —
Major axis of Orbit,	3,426,200,000 —
Minor axis of Orbit,	826,900,000 —

As shown in the diagram, this comet recedes from

the sun to a distance considerably exceeding that of Neptune. At the remote parts of its orbit it is always far removed from the plane of the Ecliptic on the South Side; and, alone of all known *periodical* comets, the direction of its motion is in the contrary direction to that of the planetary system, or against the order of the *Signs*. We have purposely dwelt at some length on the History of the Comet of Halley: while, standing as a type of the habitudes of all Comets, it holds a position intermediate between a number of Comets of shorter period, and those whose periods are so long, that rational doubt may be expressed whether they are really connected with our system or not. The subjoined diagram represents the position of the orbits of other three—viz., the Comet of 8·8 years, or the Comet of Encke; Biela's Comet, or that of 6½ years; and Faye's Comet, whose period is 7½ years. Besides these we have the Comet of De Vico, with a period of 5½ years; the Comet of Brorsen, with a period slightly larger; the Comet of D'Arrest, whose period is scarcely 6½ years; as well as six others, the probable periods of four of which are within six years,—those of the other two, being *twelve or fifteen*. Four Comets are known, with probable periods corresponding to that of Halley's; and the following results of computation may perhaps be accepted as wide approximations, viz.:—

Years of the Comet's appearance.	Probable period.
1763,	7,334 years.
1769,	2,090 —
1807,	1,714 —
1811 (the great comet of),	3,065 —
1811 (second comet of), ...	876 —
1822 (fourth comet of), ...	5,444 —
1825 (great comet of), ...	4,386 —
1840 (fourth comet of), ...	344 —
1844,	102,050 —
1846 (De Vico's),	2,720 —

There is one other Comet, apparently periodical, of too important a character to permit us to omit notice of it. One of the greatest meteors of this sort, mentioned in history, appeared in the middle of 1262; and has been spoken of by all historians in terms of wonder and astonishment. In 1556 a prodigy of the same character, and with similar elements—in as far as wide observations enable us to judge—spread terror alike over Europe and Asia. Considerable probability exists that it had appeared several times previously, after similar intervals. Some modern inquirers, especially Mr. Hind, have occupied themselves earnestly with the question of its orbit; and the latter Astronomer, after great research and pains, has ventured to say that between 1856 and 1860 we may look for its return—its mean period being about 800 years. If this prediction be verified, it will be only second in interest to what befel in the case of Dr. Halley.—Of course it must not be imagined that the larger periods mentioned above, are determined with absolute accuracy; nay, it is even unlikely that the greater number of these bodies

that visit our system, have re-entering orbits at all. It is more probably, their paths are hyperbolic; and the meteors themselves merely bent around our Sun, whose attraction they have encountered, as they sweep through the cosmical spaces. Those of them that really move in Ellipses, and therefore in one respect may be said to belong to our system, are not improbably also cosmical meteors, whose paths have been converted into Ellipses by the influence of the Sun and the Planets. Lexell's Comet, for instance, from being a very erratic meteor, was thus obliged for a brief time to revolve through a short ellipse; but the perturbing action of Jupiter again threw it off towards remote abysses. It is rendered still farther probable that the Comets do not properly belong to our planetary scheme, by the fact that they are not subject to any of the constituent laws of that scheme. For instance, they are not confined to the plane, in the neighbourhood of which the planetary orbits are all found; i.e., their places in the sky have no connection with the Zodiac; their motions are as frequently retrograde as direct; and, as we have seen, the elongation of their orbits causes them to intersect the paths of all the regular attendants on our Sun.—We can form no conception of their numbers. Probability alone is the ground of any judgment on the question; and certainly we cannot place the inferior limit, lower than many millions. The likelihood is that they are countless as the stars themselves; and must be regarded as scattered through the interstellar spaces, where they perform functions that are at present utterly unknown.

(2.) *Comets, certain Physical Features of.*—We are not yet in a condition to define the physical structure of comets. They furnish, and probably will long furnish, in this point of view, the greatest stimulus to curiosity. But a few remarks may be safely ventured on.—First, the relation of the Comets to Light cannot be considered settled by the observations of Arago. Testing the light sent by them by means of his polariscope, he discovered that it is polarized by reflection; and he hence concluded that they are not self-luminous, but that—like the planets in this respect—they shine by reflecting solar light. Arago did not show conclusively that all the light issuing from Comets is polarized by reflection; and it can scarcely be denied that what Bessel saw, regarding Halley's Comet in 1835, establishes a strong probability that these bodies have a certain faculty of evolving a proper light of their own. Further observation is needful for the settlement of this delicate question.—Secondly:—As to the molecular constitution, or interior consistency of Comets, it cannot be presumed to be distinguished by much cohesion. Neither can the particles of such a body be supposed to be held together by effect of their mutual gravitation; for that would not really amount to much more than mere juxtaposition in space.

We must look, therefore, at each individual cometic molecule, in the light of an independent projectile, describing its own orbit around the Sun. This extreme looseness of texture was strikingly manifested by the recent separation of Biela's Comet into two distinct bodies or nuclei, revolving around each other; and it is perhaps the cause of another peculiarity of these bodies—viz., their remarkable contraction in size when they reach perihelion. If a number of bodies describe parabolas or very eccentric ellipses, having the same axes, and around the same central orb in their common focus, the intervals separating them will be *minima* at the perihelion; in other words, the parabolas will nearly touch or osculate each other at that region; and the molecules will again mutually recede as the group departs from the Sun. *Compression*, therefore, at perihelion, and *expansion* afterwards, are among the mechanical necessities of such a system. It scarcely requires to be stated that the *density* of Comets is quite trifling. Although they have passed quite near to the smaller bodies of our planetary system, they have never impressed any palpable or measurable *perturbation*. But, *Thirdly*—Notwithstanding the amount of light thus thrown on such molecular expansions and contractions, the whole subject of the tails of these bodies is enveloped in mystery. These extraordinary appendages are perhaps often hollow, and symptoms of rotatory motion around their longer axes have been detected; still, why is it that they are always directed right away from the Sun; and what conceivable force can retain their more distant portions in any orbit, when at perihelion, they are brandished around our Luminary with a velocity so unparalleled? It is useless at present to waste time in conjecture on a subject, demanding, beyond everything, the attention of the precise observer. One remarkable contribution to positive knowledge must, however, be mentioned—viz., Bessel's memoir on the phenomena, attending what seemed the process of the formation of the tail of Halley's Comet in 1835. This distinguished person had rare opportunities to notice these phenomena; and they led him to the conviction that our central orb develops a *Polarity*, or exercises a *Polar Force* over these diffuse meteors. What that polar force is, remains of course unknown: but, considering it akin to *Magnetism*, it will readily be seen that it renders comprehensible the disturbance of the Comet's form, its position towards the Sun, and the fact that the motions of the body are not disturbed by the development of the tail. The whole of the memoir in question is worthy of more attention than it has hitherto received.

(3.) *Comets, as Instruments of Discovery.*—These bodies, we have said, are yet likely to lead in, brilliant courses, of otherwise inaccessible discovery. For instance, if the speculation, just alluded to, shall turn out well founded, they reveal a new character of the Sun. or at all events greatly

COM

extend our knowledge of that portion of his efficiency to which we owe all the magnetic phenomena of the Earth. In the next place, wandering, as Comets do, through all portions of the interplanetary spaces, they must doubtless unfold, in future times, the contents of these spaces;—a train of discovery that may be deemed already inaugurated by the more than presumption, obtained from the retardation of Encke's Comet, in favour of the opinion that a *resisting medium* exists. And lastly, they stand to us as specimens—the most palpable we can obtain—of those other curious formations, such as the Zodiacal Light, which belong to our planetary scheme as indefeasibly as the Planets themselves. What is already established, has, of course, dispelled all delusions as to the effects of the shocks of Comets in producing geological catastrophes in the Earth. Their feeble or rather inappreciable density, deprives them of the power to produce any dynamical effects; although it is possible that *collision*—as it has been termed—by introducing extraneous substances into our terrestrial atmosphere, might influence the fates of the organic races, to whose development and welfare that Atmosphere is an essential ministrant.

Commensurable. Two quantities of the same kind, or two numbers, are said to be commensurable when a third quantity or number is contained in each a certain number of times. In reasoning regarding *incommensurables*, we require to show that, what we expect regarding them, holds good, almost perfectly, with regard to two commensurables on each side of them; and approximates more and more nearly to the complete expression of the truth, the nearer these close in on the incommensurable in question.

Compass. Consists fundamentally of a magnetized needle turning freely. As this turns towards a position, constant within certain limits, wherever it may be, it is evidently possible, by means of it to ascertain definitely the directions and changes of direction of any motion, referring their lines to this constant direction. It is supposed commonly to have been invented about 1302, by Flavio Gioja. It was certainly known in some parts of Europe before 1180. (*Encycl. Metrop.*) Its use to sailors, who must lose all the ordinary marks of direction, is abundantly plain.

Points of the Compass are the thirty-two principal points of division on the rim of the circular card below the horizontal plane in which the needle is permitted to move freely. They are called otherwise *Rhumbs*. They are marked at the extremities of equal arcs of the circumference, and refer, according as they are nearer one or other, to the two chief lines North (towards the pole star, or North point of horizon,) and South, and East and West, (to the right and left as we look towards the North). They are as follows:—

COM

North.	East.	South.	West.
N. by E.	E. by S.	S. by W.	W. by N.
N.N.E.	E.S.E.	S.S.W.	W.N.W.
N.E. by N.	S.E. by E.	S.W. by S.	N.W. by W.
N.E.	S.E.	S.W.	N.W.
N.E. by E.	S.E. by S.	S.W. by W.	N.W. by N.
E.N.E.	S.S.E.	W.S.W.	N.N.W.
E. by N.	S. by E.	W. by S.	N. by W.

The student may readily construct the circle and mark the points in order. Each division contains $3\frac{3}{4}^{\circ}$ of the circumference, or represents $11^{\circ} 15'$ of angular space. Each is further subdivided into quarters.

Compass, Mariner's.—The common construction is of extreme simplicity. There is merely a circular box containing a paper card, on which the points of the compass are marked, above the middle of which a magnetic needle is set, free to rotate round its centre. It turns always nearly to the north, (see **MAGNETISM** and **VARIATION**,) and the amount of deviation is pretty accurately estimable.

As in all other instruments of extreme importance, this idea has been so elaborated that the chances and limits of error, from defective suspension and the like, are excessively slight. The most important irregularity that is yet beyond the complete control of practical men, arises from the effect of the iron and magnetizable matter present in ships. Many vessels are now, of course, entirely constructed of iron. In the various positions of the ship, they become magnets, acting conjointly with the earth on the needle, and exerting greater or less deviating effect, as the direction of their action coincides more or less closely with the constant direction of terrestrial magnetism. See **COMPOSITION OF FORCES**.

Azimuth Compass has the circumference of the card more accurately subdivided into exact degrees, minutes, and seconds, and to the box is fitted an index with two sights—that is, upright pieces of brass set diametrically opposite one another, with slits down the middle, through which the sun or a star may be viewed. The position into which the index of sights must be turned to see it, will evidently indicate on the card the azimuth of the star. As in all similar instruments, telescopes accurately adjusted are used instead of sights when the observation is to be exact. The use of the instrument is chiefly to note the actual magnetic azimuth, from which—as we know the azimuth calculated from the north and south line, we find the *variation* of the needle, with the amount of its changes of variation.

Compass, Deviation of, is the angle by which the compass is deflected from the magnetic north by the action of the iron in a ship.—The large quantity of iron now used in the construction and equipment of steamers, iron sailing vessels, and sometimes of wooden sailing vessels, produces a deviation of the compass from the magnetic north, which interferes seriously with

the navigation of such vessels. We shall endeavour to explain the causes, the laws, and the methods proposed for correcting the deviation so produced. All iron, as regards magnetism, is between the two extreme states, denominated "soft iron" and "hard iron." Soft iron is iron which becomes instantly magnetic by induction when exposed to the influence of any magnetized body, and instantly loses its magnetism when the influence is removed. Its magnetism is termed "induced" magnetism. Hard iron is iron which does not, in ordinary circumstances, become magnetic by induction, and which, when once magnetized, retains its magnetism when the inducing body is removed. Its magnetism is termed "permanent" magnetism.—Neither extreme exists in nature, but much of the iron in all vessels approaches each extreme. Much is in an intermediate state, the magnetism of which has been called "subpermanent," or "retentive." Such iron, when once magnetized, retains its magnetism with little loss for a long time, unless exposed to blows or strains, changing its magnetism slowly and gradually when exposed to a new inducing cause, as for instance, when the vessel changes her magnetic latitude.—In investigating the action of iron on the compass, it is convenient to suppose, in the first instance, that all the iron is "hard" or "soft," and then make allowance for the difference of the supposition from the truth. We shall first consider the effect of the permanent magnetism of hard iron on the compass, and we shall suppose the ship to remain upright—the effects of heeling not having been sufficiently investigated to be capable of being treated of satisfactorily here.—A piece of hard iron magnetized, in other words, a magnet, placed in any position in a ship, attracts the north end of the compass, in a direction in the ship which does not alter as the ship swings round. Any number of such magnets, in other words, all the hard iron of the ship acts similarly, and gives rise to a single resultant, attracting the north end of the compass in a direction in the ship, which does not change as the ship is swung round. When this resultant is in the direction of the magnetic needle, it produces no deviation. As the ship swings, the needle follows the resultant, its deviation, or rather the sine of its deviation, increasing as the sine of the horizontal angle between the needle and the resultant.—In what follows, we shall suppose the deviation to be so small that the sine of the deviation varies as the deviation, and that the deviation produced by all the disturbing forces, is the sum of the deviations they would produce separately. This simplifies the problem, and is sufficiently correct in those cases in which alone great nicety is possible.—The force which opposes the deviation or the directive force of the needle, being proportional to the horizontal magnetic force of the earth, the deviation produced by the hard iron is proportional to

Hor. force of hard iron
 Hor. force of earth \times sin angle between

resultant and needle.—Calling the horizontal force of the hard iron R , and resolving it into two,—viz., P directed towards the ship's head, Q to the starboard side; and calling the horizontal force of the earth H , and the angle which the ship's head is to the east of the deviated needle ζ' , it will easily be seen that the deviation produced by the hard iron is proportional to

$$\frac{P}{H} \sin \zeta' + \frac{Q}{H} \cos \zeta'.$$

The effect of the soft iron is less simple.—In estimating it we make the supposition, which is not far from the truth, that induced magnetism is proportional to the inducing force, and that therefore the effect of any number of inducing causes is the sum of the separate effects. The ordinary cause in this case is the earth's magnetism acting in the line of the dip; which inducing force we may resolve into its two components, the vertical and horizontal forces, and consider their effects separately.—The vertical force induces in the soft iron a magnetic state which does not change as the ship swings, and therefore produces a deviation following the same law as that caused by the hard iron. The deviation so produced, is therefore directly proportional to the vertical force, and being as before inversely proportional to the horizontal force, it varies as the ratio of the vertical to the horizontal force, i. e., it is proportional to the tangent of the dip. Calling the dip θ , and treating this force as we treated the permanent magnetism, we may represent the deviation caused by the inducing force of the vertical part of the earth's magnetism by the formula

$$B' \tan \theta \sin \zeta' + C' \tan \theta \cos \zeta'.$$

Combining the two, we get for the deviation caused by the permanent magnetism, and the vertical part of the induced magnetism

$$\left(B' \tan \theta + \frac{P}{H} \right) \sin \zeta' + \left(C' \tan \theta + \frac{Q}{H} \right) \cos \zeta'.$$

The effect of the horizontal force is most clearly seen by considering its effects on masses of iron of a simple shape,—viz., thin iron rods placed horizontally. When such a rod is at right angles to the magnetic meridian, it is not magnetic. In any other position, its south end attracts the north end of the needle; its north end repels it. Such a rod placed in the line of the keel, and either before or abaft the compass, will produce no deviation when the ship's head is either N. or S., because though it attracts the needle, it does so in the direction in which the needle is point-

ing; so it will produce no deviation when the ship's head is E. or W., because the rod is then not magnetic. When the ship's head is N.E. or S.W., it produces a maximum easterly deviation; when N.W. or S.E., a maximum westerly. It therefore causes a deviation proportional to the sine of $2\zeta'$. Here the force producing the deviation, and the force overcome in producing, are both the horizontal force of the earth's magnetism. The deviation produced, is therefore independent of this force, and may be represented by $D \sin 2\zeta'$, where D depends solely on the distribution of the soft iron in the ship. A similar bar placed athwartship, either to the starboard or port side of the compass, will produce a deviation $-D \sin 2\zeta'$; so a horizontal thin rod, whose direction passes through the compass, and makes an angle of 45° with the line of the keel, will cause a deviation $E \cos 2\zeta'$; and two similar bars similarly placed, whose direction passes through the centre of the compass, but which are at right angles to each other, will counteract each other's effects.—There is a remarkable arrangement of such bars, which remains to be mentioned,—viz., two horizontal rods, at right angles to each other, in the same plane with the compass, tangents at one end to a circle concentric with the compass. If these rods both lie to the right from the respective points of contact (looking from the centre of the compass), they produce a constant easterly deviation; if both to the left, a constant westerly deviation. This deviation may be represented by a constant term A , which will be positive in the first case, negative in the second.—These arrangements combined will therefore produce a deviation

$$A + D \sin 2\zeta' + E \cos 2\zeta'.$$

It may be shown that, whatever be the arrangement of the soft iron, the deviation produced will follow the same law, and be expressed by the same formula.—The whole deviation produced by the hard and soft iron may therefore be expressed by

$$\begin{aligned} \delta = A + \left(B' \tan \theta + \frac{P}{H} \right) \sin \zeta' \\ + \left(C' \tan \theta + \frac{Q}{H} \right) \cos \zeta' \\ + D \sin 2\zeta' + E \cos 2\zeta' \end{aligned}$$

and this formula (which may be written) $\delta = A + B \sin \zeta' + C \cos \zeta' + D \sin 2\zeta' + E \cos 2\zeta'$ will be found in all cases to represent the deviation with sufficient accuracy.—We will now return upon our steps by considering the causes and effects of the terms separately. A expresses a constant deviation whatever be the direction of the ship's head. It cannot arise from permanent magnetism. It may arise from the

induced magnetism of soft iron arranged in the way described above, and will in fact exist whenever any elongated horizontal mass of iron is placed near the level of the compass, with its ends at unequal distances from the compass. Thus it has been observed to have a considerable value in gunboats, in which a gun carriage and the fly-wheel of the pump are placed in such position relative to the compass; but it may also have an apparent, not a real value, caused by an index error in the compass on board, from an error of the shore compass from comparison with which the deviation is deduced, or from any mistake as to the amount of variation when the deviation is deduced from the observations of heavenly bodies at sea. In ordinary cases the value of A is so small, that, for the purposes of navigation, it may be safely neglected. D and E cannot arise from permanent magnetism, but only from the magnetism of soft iron. Positive values of D from such masses before or abaft the compass—negative values from such masses on the starboard or port side—values of E from masses of soft iron in the intermediate angles. As might be expected, the value of E is generally very small, and it may always be safely neglected. D varies from 1° or 2° in wooden steamers to 5° or 6° in iron steamers. By theory it ought not, and in practice it is found not to change its value in a change of latitude. This part of the deviation, has been called by Mr. Airy the quadrantal deviation, and it is convenient so to distinguish it. It is almost always positive, showing that it arises from masses of iron before and abaft the compass, and indicating that it may be corrected by a bar of soft iron, or an elongated box of iron chain, placed athwartship on the starboard or port side of the needle.—The remaining terms are by far the most important, and the most difficult to deal with. This part of the deviation has been termed the polar-magnet deviation by Mr. Airy, but is more conveniently termed the "semicircular" deviation, as it consists of two parts, one caused by the permanent magnetism of the hard iron, which is more strictly polar magnetism, the other by the induced magnetism of the soft iron. These two parts change, but in different proportions, with a change of magnetic latitude. The first varies inversely as the horizontal force. The second varies as the tangent of the dip.—Their changes in different magnetic latitudes may be thus described:—At a magnetic pole of the earth, when the dip is 90° , and the horizontal force zero, each part becomes infinite. This indicates that there is then no directive force. For some distance from the magnetic pole the two parts change nearly at the same rate, and therefore the whole varies nearly as the tangent of the dip. But as we approach the magnetic equator, the part which arises from the soft iron diminishes the most rapidly. It becomes zero at the equator; and in south magnetic latitudes has the same value as in corresponding

north magnetic latitudes, but the opposite sign. The part which arises from the hard iron does not become zero at the magnetic equator, but becomes a minimum at that line, nearly coincident with the magnetic equator, at which the horizontal force is a maximum, and in south magnetic latitudes it has the same sign, and nearly the same value, as in northern.—If our hypothesis, that all the iron is perfectly hard or perfectly soft, were strictly true, it would be possible by observations made in any two magnetic latitudes to determine the values of the two parts separately. But in fact this is impossible. The subpermanent or retentive magnetism causes the changes in the magnetism of a ship to depend not only on the place at which the ship is, but on the places in which she has been for some preceding days or weeks; her magnetism being thus in arrear of its theoretical amounts, to an extent which there appear to be no means of estimating.—It appears to have been established by Dr. Scoresby, that a change takes place in a newly launched iron vessel, even without a change of magnetic latitude; but it seems probable, that, after a short time, and a few voyages, no further change of any importance takes place without a change of magnetic latitude.—We shall now say a few words as to the phenomena observed in different parts of the same ship, and the methods of correction which have been proposed. In general, in north magnetic latitudes the north point of the compass is attracted towards, and follows, the ship's head. This arises from the larger mass of iron before and below the compass. As the upper end of every vertical mass of iron attracts, and the lower end repels the north end of the needle, the funnel, the lower end of which is generally before the standard compass, generally diminishes the attraction, and acts as a corrector. An iron stern post is still more effective, and frequently more than counteracts the effect of all the iron in front of it, causing the north point of the compass to follow the stern of the ship. In such a case we may generally find a place in the ship, before the stern-post, where the semicircular deviation is zero. But placing the compass in such a position is of less advantage than might be supposed, as a change would probably take place on a change of latitude.—Whatever be the amount of the semicircular deviation, it may be easily corrected at any given time and place, either by a bar of soft iron, as proposed long ago by Capt. Flinders, or by a magnet, or two magnets, as proposed more recently by the present Astronomer Royal. The methods of making these corrections are too well known to require description here. These corrections may be useful when the vessel does not change her magnetic latitude materially, as in the case of vessels plying between ports in the United Kingdom, or even in Europe, or plying between England and the United States, but are worse than useless when the vessel changes her magnetic

latitude considerably, more especially when from a northern she goes to a southern latitude. In fact, whenever the semicircular deviation is reduced to zero by the addition of either soft iron or a magnet, it can only be by the induced magnetism of the soft iron (including the soft iron corrector if applied), compensating the permanent magnetism of the hard iron (including the correcting magnets if applied).—The consequence is, that, in a ship, whose compass has been so corrected, going to an equal south magnetic latitude, the induced magnetism of the soft iron changing its sign, doubles instead of compensating the magnetism of the hard iron. The danger of all such corrections is so well understood in the Royal Navy, that no such correctors are ever made use of in her Majesty's ships, but they still continue to be made use of in the mercantile navy, not only in vessels plying between different ports nearly in the same magnetic latitude, but even in vessels going to southern latitudes. As an instance of the inefficacy and danger of such corrections, it may be mentioned that the Fiery Cross iron steamer had her binnacle compasses corrected by magnets in England, and in latitude 29° 58' S., longitude 60° 39' E., had a deviation of 85°.—How then are the deviations to be corrected? By fixing a compass, to be called the standard compass, in a place in the ship as far removed as possible from the disturbing influence of the ship's iron, directing the ship's course by this, and using the binnacle compass merely as a guide to the man at the helm. It has been proposed to fix such a compass at the mast-head, fitting the mast-head with brass work instead of iron work; and it is said that a compass may be so fixed, and then observed without inconvenience; and that when so fixed, the deviations are insensible. This method was successfully adopted in the "Royal Charter," as described by Dr. Scoresby. If not adopted, or not successful, the method adopted in the Royal Navy is to be preferred. An azimuth compass is fixed at a convenient place so high above the deck that bearings can be taken over the ship's bulwarks. Then the ship's head should be placed on a number of compass points, as nearly equidistant as possible, and the deviations on each point observed either by comparison with a compass, or by the bearing of a distant terrestrial object, or of a heavenly body. The methods of doing this are well known, and are described in a pamphlet published by the Admiralty, under the title, *Practical Rules for ascertaining or applying the Deviation of the Compass caused by the Iron in a Ship*. From these observations a table of compass-courses and corresponding correct magnetic-courses may be formed, by which (making a simple interpolation if necessary), from any compass-course, the corresponding correct magnetic-course may be found, or, conversely, from a correct magnetic-course, the corresponding compass-course.—This is suf-

ficient for ordinary purposes. When greater accuracy is required, then we have the two problems to solve,—viz., *first*, from deviations observed on a few points to compute the deviation on the intermediate points; and, *second*, from deviations observed on a large number of points to compute the most probable value of the deviations on each point. These may be solved mathematically by computing the co-efficients $A B C D E$ from the observations, by the method of least squares; and when the observations are made on equidistant points, the calculations are very simple. The method of doing this is given in a "Supplement" to the "Practical Rules," by Archibald Smith, Esq., published by the Admiralty. Another method, which is the most convenient in ordinary cases, is the graphic method, proposed in different shapes, by Mr. J. R. Napier of Glasgow, and Captain Ryder, R.N.—In this method a straight central line of convenient length—say 18 inches—divided into 360 equal parts, represents the margin of the compass-card cut at the north part, and straightened and extended in the following way:—

N. E. S. W. N.

Through any compass-course taken on this line, and the corresponding correct magnetic-course, two straight lines are drawn intersecting in a point above the central line if the deviation be east, below if west.—Through every compass-course, on which the deviation has been observed, lines parallel to the first set are drawn, and through every corresponding correct magnetic-course, lines parallel to the second, giving a point of intersection for each observation. Then a curve is drawn, called the curve of deviations, passing as nearly as possible through all the points of intersection. We have then the following easily applied solution of the two following problems:—

PROBLEM I. From a compass-course to find the corresponding correct magnetic-course.

Rule.—On the central line take the compass-course. Move parallel to the first set of lines till you reach the curve, then parallel to the second set of lines till you get back to the central line. The point in the central line, at which you arrive, is the correct magnetic-course required.

PROBLEM II. From a given correct magnetic-course to find the corresponding compass-course.

Rule.—On the central line take a given correct magnetic-course, move in a direction parallel to the second set of lines till you arrive at the curve, and then move in a direction parallel to the first set of lines till you get back to the central line. The point on the central line at which you arrive is the compass-course required. In Mr. Napier's plan, both sets of lines make an angle of 60° with the central line, and with each other, so that the lines form a set of equilateral triangles, and the scale on each line is the

same as the scale on the central line.—This method is described with diagrams in the "Supplement" to the "Practical Rules" above mentioned, and is also published separately by the Admiralty, under the title, *A Graphic Method of Correcting the Deviation of a Ship's Compass*. In Captain Ryder's plan, the central line is the diagonal of a square, the other lines make angles of 45° with it, and are at right angles to each other, and to the sides of the square, which sides are divided into 360° . The top and bottom representing correct magnetic-courses, the sides compass-courses.—By this method the correct magnetic-course corresponding to a given compass course, or the compass-course corresponding to a given correct magnetic-course is found as if by a table of double entry. A description of this method, with a diagram, has been published by the Admiralty, as a supplement to the "Practical Rules." The two methods, it will be seen, are the same in principle. Mr. Napier's will perhaps be found more convenient in construction by the expert, Captain Ryder's more simple in use by the inexperienced.—When the deviation is corrected either by a table or by the graphic method, it must be remembered that the same table or the same curve can only be used so long as the ship remains in the same magnetic latitude, and so long as there is no material change in the arrangement or condition of the iron of the ship. *Whenever any considerable change in the magnetic latitude of the ship takes place, a fresh table should be computed, and a fresh curve constructed from fresh observations.* It should be mentioned, that plans have been proposed for correcting the semicircular part of the deviation by adjustable magnets, which can be readjusted on a change in the deviation; but it seems doubtful how far it is prudent to entrust such delicate manipulation to unskilled hands. Since the first edition of this work, the journal of Dr. Scoresby's voyage to Australia in the "Royal Charter" has been published. This voyage was undertaken with the object of observing the change in the magnetism of an iron ship proceeding from a northern to a southern magnetic latitude. The result showed a change in the compasses corrected by fixed magnets of about one point on the arrival of the ship in Australia, and of two points on its return, and a consequent failure of this mode of correction, indicating a large change in the sub-permanent magnetism. The change did not indicate the existence of any large amount of transient induced magnetism.

Compensation. A method adopted in many cases to neutralize errors of which we cannot get rid. Thus, if we wish to obtain a residual phenomenon, free from some slight effect of irregularity, we introduce an opposite irregularity of nearly equal amount. The compensation balance of a watch, and the methods adopted for preventing the deviation of the ship's compass

from the magnetic meridian, are beautiful instances of this;—the former tolerably complete, the latter but very partially so as yet. The compensation pendulum illustrates the principle sufficiently. See CHRONOMETER.

Complement. In *Arithmetic*, the complement of a number is the difference between it and the power of 10 immediately above it: thus, 473 is the complement of 527. In *Geometry*, the complement of an angle is the excess of a right angle over it.

Composition of Motion and Forces.

Resolution of Motion and Forces.—The very important mechanical and physical problem usually designated as above, is equivalent to this:—If a Body in Motion becomes subjected anyhow to a second motion; or, if, to the Force impressing the first motion, there be superadded as effective on the Body, a second Force, naturally causing a Second Motion—what will be the actual Motion of the Body? Or what the Single Force, in obedience to which, it may be supposed to move?—I. The formal reply is this:—1. With regard to its motion of TRANSLATION. If a

body, disposed by any force to move through the space A B, along the line A B, in a given time, should also be subjected to the operation of another force, tending to cause it move in the same

time, through the space A C, along the line A C it will actually move in that specified time through the line A Z—the diagonal of the parallelogram formed on A B and A C, as its sides. And supposing the body A subjected to three forces, lying in different planes in space, it will move, in the unit of time, along and through the diagonal of the parallelepiped, formed by three lines representing, in direction and amount, the three elementary forces. By an easy application of this fundamental theorem, any number of Forces acting at a point may be compounded and their influence represented by a Single Force; and, vice versa, any Single Force may be conceived as the Resultant of any number of constituent elementary Forces; and resolved into these elements. 2. To the case of Motion of ROTA-

tion, or of Forces causing Motion of Rotation, a similar principle applies. Technically, this part of the general problem consists in the *Composition and Resolution of Couples*. The nature of the solution will be understood by a single illustration, viz.; if a body, A (see preceding figure), rotates from west to east, around an axis whose direction is A C, and with a velocity represented by the line A C; and if it be struck anew by a force, that of itself would cause it to rotate also from west to east, around an axis whose direction is A B; and with a velocity represented by the line A B; then it will actually rotate from west to east, around an axis whose direction is the diagonal A Z, and with a velocity represented by A Z. In the same manner, rotations lying in different planes, and

whether in the same or in opposite ways, may be compounded, and of course resolved at will, precisely as with Motions of Translation.—II. The inquiry, as to the grounds on which the principle just enunciated reposes—the proposition usually termed the *Parallelogram of Forces*—has been a favourite and fertile one, with persons occupying themselves concerning the Philosophy of the Sciences. We have no room for controversy; and shall merely record our conviction, that the principle formally expressed by the Parallelogram of Forces is not resolvable into any simpler one; and that the proposition itself, is therefore not deducible, in the strict sense of the term. It is an Axiom, commended by universal experience, that, if a moving body be impressed with a new motion, or acted on by a new force, it is not thereby hindered from obeying to the full, alike in quantity and direction, the first motion to which we have supposed it subjected. For instance, whether a ship is at rest or sailing smoothly, all interior motions—actions, let us say, on its deck—take place indifferently, and with the same precise results. Now, the Parallelogram of Forces is nothing more than the technical rule, to which this principle gives rise. It will be found, on exact analysis, that every effort to deduce the principle *a priori*, whether geometrically, or by aid of the algorithm of Functions, involves some assertion fully equivalent to the truth pretended to be demonstrated.

Compressibility. Bodies are supposed to be constituted of small indivisible atoms, existing at certain distances from each other, but kept together by attractive forces within the body, as solids; or by coercive forces from without, as liquids or gases. In all cases, except in the case of these indivisible atoms themselves, bodies are supposed to be made up of a number of these particles. All cases which come practically under our observation are included under this statement, for whether or not these atoms exist at all, they have never been found as magnitudes recognizable by our finest senses, assisted by our most perfect instruments. Every body, then, is composed of atoms at certain distances from one another.

From this statement we are naturally led to inquire if these distances can be augmented (see EXPANSION) or diminished. That property of bodies, in accordance with which they can be diminished is called their *compressibility*.

The compressibility of different bodies is different. The relative compressibility of various bodies is readily tabulated, according to the degree of compression obtained by the application of a given force. One thing, however, must be observed carefully. The compressibilities must be measured at one uniform temperature. There is no property of bodies more readily and completely altered than this is, by the influence of heat. Thus water at 212° becomes steam, and is then compressed according to the gaseous laws, in the inverse

COM

proportion of the pressures applied, becoming $\frac{1}{5}$ less by the addition of one atmosphere of pressure, while water itself scarce becomes $\frac{1}{100000}$ th less, as we shall immediately see. A heated solid generally takes up much more space than a cold one; and hence the body exists with its particles at greater distances one from the other in the first case than in the second. In this case also they are generally more compressible by outward force. The extraction of heat, indeed, without the application of outward force, produces in almost every case, a degree of compression and *vice versa*. Compression, in almost every instance, is accompanied by evolution of heat. The degree of compression, at given temperatures, varies in solids, according to their other physical properties. A like variation obtains for liquids. They were originally thought indeed to be incompressible. The celebrated experiment of the Florentine Academicians, in which they applied very great force to a ball of thick gold filled with water, in order to compress the water, and found themselves only able to make it ooze through the metallic surface, was held to be conclusive upon the point. But this was very soon doubted. What it did, in fact, prove, was, that it requires a less force to drive water through the pores of gold than it does to compress its bulk. It has been questioned whether it even established this, or whether the percolation of water was not due rather to cracks and fissures in the gold than to the severe pressure to which it was submitted; fissures so small, as not to be visible to the experimenter. Even accepting the other conclusion, we are not forced to believe water and other fluids incompressible. In fact we see that the diminution of heat does compress them, and knowing as we now know, the identity of the nature of heat and mechanical action, this would be sufficient to prove that they are compressible in certain circumstances. But without falling back on this resource, experiments made more carefully than the Florentine one, have shown very clearly that liquids are compressible. Water, for example, has been compressed by the addition of a pressure of 15 lbs. per square inch to the atmospheric pressure (addition of *one atmosphere* of pressure) to lose $\frac{1}{100000}$ th of its bulk. It loses by the addition of two atmospheres proportionally more and so on. This law holds, within the limits under which we can safely experiment. We cannot procure pressures of a thousand atmospheres, or construct vessels capable of withstanding them. Pressures of 800 atmospheres have been applied. Other liquids follow the same law, each having a different coefficient of compression for the increase of an atmosphere in pressure.—With gases the case is different. The bulk of gases increases or diminishes in exactly inverse proportions to the pressures. Thus, if we add a pressure of one atmosphere to a gas, it will be reduced to one-

CON

half of its original bulk, if a pressure of four atmospheres, to one-fifth, and so on. This law holds for all gases within certain limits. Under violent pressures gases evince a tendency to assume the liquid form. When they reach pressures near those at which they actually pass from the gaseous state, the foregoing law becomes very little reliable. In some instances such passage to fluidity is the result of pressure comparatively slight; with others again, it has not been found possible to procure any indication of an approach to it, by our highest available pressures. Thus the following gases are condensed into liquids at the pressures noted:—

GASES.	
Sulphurous Acid Gas,.....	2 atmospheres.
Cyanogen,.....	3 "
Ammonia,.....	5 "
Sulphuretted Hydrogen,.....	15 "
Muriatic Acid,.....	24 "
Carbonic Acid,.....	36 "
Nitrous Oxide,.....	44 "

If, however, we keep in mind, in the case of each gas, its point of transformation; we may safely apply the gaseous law above stated to all pressures sensibly lower.

Concave. A surface is said to be *concave* where lines, drawn from point to point in it, fall between the surface and the spectator; and *convex*, where the surface comes between the spectator and these lines. By changing our position one surface may thus become to us successively concave and convex. They are merely relative terms. See LENS and MIRROR.

Concord, in Music. For an explanation of the meaning of this, and of the circumstances in which it obtains, see HARMONICS: for an explanation of the theory, see ACOUSTICS.

Condenser, Electric. The use of this highly valuable instrument is so far indicated by its name. The immediate result which is contemplated in every proper employment of the condenser, is the condensation of electric charges; or, in other terms, the increase of electric tension. It may be added, that the final results most generally aimed at, in the employment of the instrument, are electroscopic and electrometric determinations, in regard to very feeble charges or sources of electricity. And it is, indeed, the extreme importance of such determinations that renders the condenser so valuable as an instrument of research. Suppose, in illustration of these remarks, that a charge has been distributed over such an extent of surface that its existence cannot be detected by the employment of any simple electroscope, such as the electric pendulum. For determining the existence and the species of a charge so diffused, the only known method is to accumulate the charge, or some part of it, upon a much smaller extent of surface than it originally occupies. This accumulation is the work of the condenser. Then, by a simple change in the conditions of the apparatus, we detach the accumulated charge from the original

CON

surface, and make it act on the electroscope. In further illustration, consider a much more important case than the preceding. Every electric source, with which we are acquainted, is incapable of evolving electricity beyond a certain tension, which depends upon the nature of the source. If the limiting tension, then, which corresponds to any particular source be very feeble, the static electricity evolved by the source can be detected only by a process of accumulation, as in the former case. The instrument and the process of accumulation are the same in both cases. The condenser draws in fact upon the source, as upon a very great conductor very feebly electrified. These examples indicate to some extent the importance of the functions of the condenser in electro-statical experiment. They indicate also that as far as electroscopic purposes are concerned, the work of the condenser is just to increase a given charge in a greater or less proportion according to the power of the instrument. Consider now in what way these important results are effected. The condenser consists essentially of three plates in the form of discs with plane and polished surfaces. One of the discs is formed of insulating matter. The other two are conductors. In the adjoined figure there is a representation of

the condenser in the form in which it is most commonly employed. The insulating plate does not appear in the figure, its place being supplied by thin shells of non-conducting varnish, which have been painted upon the surfaces of the conducting plates. As appears from the figure, the upper disc is furnished with an insulating handle, and the lower is in permanent connection with a gold leaf electroscope. The working of the apparatus is very simple. The upper disc is placed upon the lower. The former, which is called the receiving plate, is then made to communicate with the source, while the latter, or the condensing plate, is put in communication with the ground. By this disposition the given charge is placed in peculiar circumstances. A conducting path has been all but opened up for it into the ground; and it is most important to observe that the two surfaces which limit the interruption in this path are very extensive and very near to each other. It is in these circumstances that the power of the condenser originates. By the disposition above mentioned the condenser is charged. An instant of time is generally sufficient for the completion of the charge. To manifest the charges accumulated in the plates, we suppress the communication between the condensing plate and the ground, and that between the receiving plate and the source. The discs are then separated, and they are both found to be charged, the upper

CON

with the electricity of the source, and the lower with the opposite electricity. In a good condenser the intensities of the charges on the two discs differ very slightly from each other, and are much greater than that of the original charge, so much greater, indeed, that they may give powerful effects with the electroscope even when the original charge gives none. That there is a considerable accumulation of electricity in the discs is a fact that may be directly proved by experiment; but we may easily account for this accumulation from known and simple principles. The electricity of the source is diffused, first of all, over the surface of the receiving plate. It then acts by induction upon the condensing plate through the thin shell of nonconducting matter that separates them. The latter plate, being in communication with the ground, receives therefore an opposite charge of electricity. This charge reacts inductively upon that of the receiving plate, and disguises a certain proportion of it, so that an additional quantity of electricity flows into the receiving plate from the source. This additional charge increases the induced charge upon the conducting plate, and the latter charge reacts therefore more powerfully upon the receiving plate. It is an essential part of the theory of the condenser, that this process goes on, until the free charge in the receiving plate is equal to that which it would have obtained in the absence of the condensing plate. We are now in a condition to give a mathematical statement of the theory of the instrument. Let P and Q be the total accumulated charges in the receiving and condensing plates respectively. The circumstances of the charges P and Q are different. The charge Q is entirely disguised, so that if the condensing plate be touched by a conductor it parts with none of its electricity. On the other hand, the charge P consists of a disguised portion and a free portion. But the same principle may be applied to both charges, and it is this—that the total charge induced in either plate has a constant proportion to the total inducing charge in the other plate. This principle is founded on experiment, and must be acknowledged as at least closely approximating to the truth. If, therefore, Q be equal to $M P$, the disguised part of P will be equal to $M Q$ or to $M^2 P$, for the disguised part of P is the total charge induced by Q , and must be, by the above principle, in the same proportion to Q as Q is to P . The disguised part of the charge P being then $M^2 P$, the free charge upon the receiving plate must be $P - M^2 P$ or $(1 - M^2) P$; and, by a principle already stated, this is the total charge that the receiving plate would have obtained from the source in the absence of the condensing plate. If M be very nearly equal to 1, which it is in a delicate condenser, it is evident that the condensed charge P is excessively great, compared with the free charge or the natural charge $(1 - M^2) P$. In general, the ratio of the former

CON

charge to the latter, or the fraction $\frac{1}{1-M^2}$, is very properly taken as the measure of the condensing power of the instrument. With regard to the charge Q , which is accumulated in the condensing plate, it is equal to MP ; and, since M differs very slightly from unity, this charge differs very little from P . This fact excuses the disposition represented in the figure, in which the electroscope is connected with the condensing rather than the receiving plate. The disposition is required for convenience of manipulation, and it is made, as we see, at little or no sacrifice of sensibility in the instrument. After these remarks, it is evident that the best condenser is that in which M most nearly equals 1; in other terms, it is that in which Q nearly equals P , or in which the charge induced in the one disc is most nearly equal to the total inducing charge in the other disc. The entire question as to the efficiency of the condenser may therefore be reduced to this: What are the circumstances which affect the value of M , and how do they affect it? There are three elements upon which M chiefly depends—the diameters of the discs, the thickness of the insulating plate, and the matter of which the latter plate is composed. When the diameters of the discs are increased, and when the thickness of the insulating plate is diminished, M approximates to 1; but there are practical limits to this approximation. The discs cannot be properly handled, nor even properly fitted to each other's surfaces, when their diameters are too great. Practically, the most convenient magnitude of the diameters is between six inches and a foot. Again, when the thickness of the insulating plate is too far diminished, a discharge between the discs may have place through the plate. With delicate instruments, such as that represented in the figure, which are employed for the examination of very feeble charges, the thickness of the insulating shells of varnish on the surfaces of the discs is sometimes diminished to less than $\frac{1}{10}$ of an inch. The value of M in such a case must differ from 1 by an excessively small quantity. The third element which was mentioned as affecting the value of M is the matter of the insulating plate. It is proved, by Faraday's discoveries in Induction, that plates of air, glass, gum-lac, and sulphur, though of equal thicknesses, would have different effects as insulating plates in the condenser. The value of M increases, in fact, from each kind of matter to the following in the above series. The principal reason, however, for the employment of gum-lac rather than the more easily obtained medium of air, is the greater power of the former in resisting discharge through its substance—a power that renders the gum-lac safely reducible to a very small thickness when it is employed as the insulating medium. Before leaving the Theory of the Instrument, we should observe that the value of M can be easily determined for any particular

CON

condenser. When the condenser has been charged and insulated, and the plates have been separated, the total charges, P and Q on the discs, may be estimated by the Proof Plane and the Torsion Balance. The ratio of Q to P is M , and from this we easily find the condensing power $\frac{1}{1-M^2}$. Another method is, to estimate first the free charge upon the receiving plate, and then, after having touched the receiving plate with the finger, to estimate the free charge upon the condensing plate. The ratio of the latter charge to the former is the same as that of Q to P , and therefore equal to M . This useful and beautiful instrument appears to have been invented by *Æpinus*. It was afterwards improved by *Volta*, and applied by him in his delicate researches in electricity. Since the time of *Volta*, the condenser has been constantly in the hands of experimental philosophers, and has contributed in a great degree to the progress of electric science. As might be expected, the instrument has passed through a great variety of forms. Among these, there is one that deserves to be specially noticed—*Peclet's* double condenser. This instrument contains a singular addition to the common condenser—a third conducting plate, which is varnished upon both faces, and placed between the receiving and condensing plates. A charge is first induced in the middle plate, according to the common method. The receiving plate is then removed, and a charge is induced in the condensing plate, which, by its reaction, disguises the greater part of the charge which induces it. The receiving plate is replaced, and the process is repeated. The condensing plate is charged finally with the result of a double condensation. This form of the instrument is very delicate, but its indications are very uncertain, so much so, indeed, that some have spoken of the instrument as utterly useless. The figure, as we have said, represents the most common form of the instrument, as well as the earliest. In illustration of the services that have been rendered to science by the condenser, we may refer to *Volta's* detection of the electric charges at the poles of the Pile, and to *Pouillet's* beautiful investigations on the evolution of electricity in combustion and evaporation.

Conduction in Heat. Bodies do not transmit heat with the same rapidity. This can be very readily established by holding pieces of steel wire and hardwood successively in the fire for a few minutes, when the first will become too hot for the fingers, while no difference of temperature in the wood will be noticeable. The heat felt will be due merely to radiation from the fire. In the same way we may melt a glass rod in the fire or before a blowpipe; while the heat is conducted so rapidly through a silver wire that it cannot be held long in the fingers. There is, then, a difference of conducting power in bodies; and those which conduct well, are termed good

conductors, as silver and steel wire.—Heat propagated in conduction, is supposed to pass from one particle to another, which touches it. We should expect, therefore, to find some sort of relation between the density of a body and the form of its particles in contact,—and the conducting power. Sufficient indications of such relation are already found.—The methods employed to test the conducting power of bodies have been various. Thus, Ingenhousz poured boiling water into a vessel, on the sides of which were holes filled with mercury, into which thermometers dipped; and then watched the rise of the thermometers. He also coated bars of several metals with wax, and watched the rapidity with which the melting progressed, and the height on the bar to which it rose in a given time. These methods were, however, rather capable of indicating the place of a body in a list of conductors, than of ascertaining the exact proportions of their conducting power. Despretz's experiments were conducted with square prisms of the matter to be examined, all coated with the same varnish, so as to radiate similarly. Along the prisms, at regular intervals, holes were cut, and mercury, into which thermometers dipped, poured into them. The bar was then strongly heated at one extremity, and after alternating and varying somewhat, the thermometers at each point came to mark (the heat being kept still applied) a constant temperature. The range of temperatures marked in different substances gave, according to the theoretical principles wrought out by Fourier, a measure of the conducting power. An idea of the results obtained will be given by those got with a copper bar heated by the flame of an argand lamp. The numbers represent the excesses above the temperature of the room in which the experiment was performed, noted by the successive thermometers:—

1st 119°-2. 3d 58°-7. 5th 33°-5.
2d 39°-2. 4th 44°-1. 6th 33°-8.

The results at which Despretz arrived from these experiments are as follows:—

Substance.	Conducting Power.	Substance.	Conducting Power.
Gold.....	1000	Tin.....	304
Platinum.....	981	Lead.....	180
Silver.....	973	Marble.....	23.6
Copper.....	898	Porcelain.....	12.2
Iron.....	374	Fire clay.....	11.4
Zinc.....	363		

These three latter substances, however, cannot easily be experimented on, and the results given are, at best, doubtful. It deserves notice that a general law, that the more expansible and fusible metals conduct worst, appears to be indicated.—The difference of conduction is very frequently illustrated in ordinary life, when we touch different bodies at the same temperature; which, however, differs from that of the fingers. Suppose a piece of wood and of iron, both colder than the skin, to be touched—the one by the one hand,

and the other by the other. The hand placed on the iron will feel the cold much more than the other, because the iron, conducting heat more rapidly, tends more rapidly to bring down the temperature of a body in contact with it, to what it has itself. This explains why it is very difficult to light a fire in a massive metallic grate, and so easy to do so in a fire-place surrounded with bricks. The former conducts the heat away too rapidly—more so than the kindling matters can supply it; and the latter scarce at all dissipates the heat.

There are many points of view in which this difference of conducting power may be made economically important. Thus, vessels of glass and earthenware ought to be made as thin as possible where they are likely to be exposed to sudden variations of heat and cold. Test-tubes, for example, must be of very thin glass at those points where the heat is applied; if not, the outer glass contracts or expands by heat; while, from the bad conducting power, the inner part retains its heat, and therefore its extension. This is the cause of very frequent breakage in ordinary household ware. So again, in ice-houses, the walls should be built double—enclosing within, all round, a space of air which conducts very weakly, and which will, in consequence, impede the transmission of heat from without to the ice. Here the CONVECTION (*q.v.*) by which apparent conduction through air is produced is not possible, because there is not provided a constant supply of new air. The same plan is adopted in some wine-coolers, in which it is desirable to keep the temperature considerably below that of the surrounding air.

The conducting power of *liquids* is much less considerable than that of *solids*. Woods hold a sort of intermediate position between the earths and the liquids, probably because there is a mixture of both in their composition. Their conducting power seems to vary from about $2\frac{1}{2}$ to 4 times that of water. Charcoal is very remarkably nonconducting, probably from the amount of watery vapour and of air which it condenses within its mass. Liquids were not, for some time, imagined to conduct at all. They do indeed transmit heat, but it was thought that the principle of *convection* fully accounted for all that they accomplish in this way. Experiments, however, were instituted, and, although no very reliable numerical results have been attained, it has been found that, taking the conductivity of gold as 1000, that of water may be represented by 9 or 10. Comparative tables of their conducting power have not been prepared to any considerable extent. Dr. Thomas Thomson gives the following proportions:—

Water, conducting power	1	} Equal volumes.
Linseed oil, —	1.111	
Mercury, —	2	
Water, conducting power	1	} Equal weights.
Linseed oil, —	1.065	
Mercury, —	48	

Brewster's very interesting experiments upon conductivity, upon optical principles, are too complicated for insertion here. They will be found in his *Edinburgh Cyclopædia*, and in the *Philosophical Transactions* for 1810.

Gases are still worse conductors than liquids. Their conducting power is, in fact, quite insensible. Doubtless, a room very rapidly gets heated, but it is not so much by the conduction, as by the radiation of heat. Gases do, to a certain extent, unquestionably conduct, as all bodies must; but their transmission of heat is chiefly due to convection. Its existence can be readily proved by holding the hand above and below a flame, at equal distances from it. There is a constant upward current of heated air, which makes it impossible to keep it in the one position; while in the other, though the source of heat is exactly the same, and the distance also, the heat received by the hand is quite inconsiderable. The existence of some air in his vacuum, probably accounts—on this principle of convection—for Pictet's observation, that a bar, heated at the middle in vacuum, heats more rapidly upward than downward. So far this air, indeed, must have existed in the vacuum, because in the pores of every body a certain amount of it is confined, which, on being liberated, would expand out, giving a very rare atmosphere, yet capable of producing sensible effect.

A very remarkable consequence of the small conducting power of gases is, its effect upon the warmth of clothing. In the pores of clothing materials there is always a certain amount—often enormously disproportionate in volume to the other matter of which they consist—of air imprisoned. In some kinds of clothing this air is held with considerable force—in most not. But by such, the temperature of the body is not readily allowed to sink far below the average. The heat which the cold outer masses tend to take from it traverses very slowly the layer of air intervening, which is not permitted to change. The naked body is, indeed, also surrounded by such a layer, but the warm air is allowed to pass off, and be constantly supplied by new air, requiring fresh supplies. Thus the process of convection soon cools us. Clothing generally is quite capable of preventing this, and the greater the proportion of the air to the other material, the warmer is the clothing. Thus, Rumford found that a thermometer cools through 185° when embedded in the following substances, as follows:—

Seconds.		Seconds.	
Air in	576	Fine Lint.....	1032
Cotton Wool....	1046	Sheep's Wool...	1118
Raw Silk.....	1283	Beaver's Fur...	1296
Eider Down....	1305	Hare's Fur.....	1315

This represents merely the time taken when the embedding substance was not manufactured. Some of these, as we know, admit of closer texture in manufacturing—some of looser. In the

latter case the warmth is increased—in the former diminished. It was thought at first probable that these differences might be occasioned by the different natures of the silk, and lint, and wool, &c.; but it was found that the effect increased when there was less compression, and more air consequently, permitted, and diminished on compression. Radiation has some effect undoubtedly in producing this difference of warmth in clothing; but the foregoing is the chief cause of it. The same principle explains the power of snow to protect vegetation. It also is very porous, and filled like fleece with air. Conduction from the cold upper air and sky down to the snow-covered earth is therefore very difficult, while there comes up from the heart of the world to the cold surface an unchilled supply of genial warmth.

M. de Senarmont has recently published a remarkable series of experiments on the conduction of heat in crystalline bodies. Perfect crystals are usually so small, that this had been thought impracticable. He employed crystalline plates cut from the crystal, according to certain relations with the optical axis, and passed through them a silver wire heated, and kept at a constant heat, by conduction from a fire at a distance. He notes the passage of the heat across the plate, by covering the plate with a thin coating of wax, which melts as the heat advances. At any time there will be formed isothermal curves round the centre of heat; that is, curves along whose borders the heat is equal. If these be circles, the crystal will have conducted heat uniformly in all directions; if figures of other forms, not so. The outline of these isothermal curves will, at any moment, be the border of the wax which divides the melted and unmelted portions. Employing many very delicate mechanical and theoretical refinements, M. Senarmont arrived at the following results:—

1. In crystals of the regular system the conductivity is equal in all directions, and the isothermal surfaces are therefore spheres. It ought to be noticed that, instead of a *plate*, a *solid crystal* is here spoken of.

2. In the right prismatic system, with square base, the conductivity takes a maximum or minimum value in the direction parallel to the axis of the figure; it is equal in all directions perpendicular to this axis, and the isothermal surfaces are ellipsoids of revolution round the symmetrical axis.

3. In crystals of the rhombohedral system, or that of the right rhomboidal or rectangular prism, the conductivity has three values—a maximum, a mean, and a minimum—following three rectangular directions, always parallel to the axis of the crystal, and the isothermal surfaces are ellipsoids, whose three unequal axes coincide with the axes of symmetry.

4. In the system of the oblique rectangular prism, the conductivity takes three different

values, at right angles. The first is parallel to the crystallographic axis, and the second and third being connected apparently with no axis of symmetry, depend on the special nature of each individual crystal. The isothermal surfaces are therefore ellipsoids with three unequal axes, only one of which is previously determined in position.

It is only needful to state these laws to show at once the very close analogies which subsist between the propagation of heat and of light through crystalline substances.

Conduction of Electricity. A few remarks are made upon this subject, in the article on **ELECTRICITY**. In the present article, we may enter into some of the more important details. Conduction, according to the common use of the term, denotes not the transference of electricity in general, but a particular mode of transference. There are, in fact, four pretty distinct ways in which free electricity is transferred through space. These are, conduction, disruptive discharge, electrolytic discharge, and convection. The last of these modes bears the same relation to the conduction of electricity, that the convection of heat bears to the conduction of heat. We have a good example of convection in the case of an electrified conductor, insulated in air which contains floating particles of dust. The particles are attracted to the body, then electrified by discharge or contact, then repelled, taking with them a portion of the original charge. By the continuance of the action, the charge may be dissipated in a very little time. This instance illustrates the difference between convection and conduction. Electricity is transferred effectively in both ways; but in convection, the charge is transferred by remaining stationary upon a moving body, while in conduction the electricity is transferred through stationary matter. Common conduction is distinguished further from electrolytic discharge by the powerful agency of the chemical forces in the latter, an agency that affects the entire character of the electric phenomena. With regard, finally, to disruptive discharge, it is true that, from the most violent cases of discharge in this form, to the most quiescent forms of conduction, we can trace experimentally a series of cases differing little from each other; yet the common phenomena of disruptive discharge are so very distinct from those of conduction, that the two modes of transference are justly described, in general, under separate heads. The circumstances that affect the conduction of electricity are various. Among these, the most evident is the specific conducting power of bodies. When two insulated bodies are charged with opposite electricities and connected by a rod that touches both, the result depends upon the species of matter of which the rod consists. With one kind of matter the charges remain on the original surfaces, with another kind they unite through the rod, and are neutralized in whole or part. We say, therefore,

that one rod has a greater conducting power than another. With limitations to be afterwards mentioned, it is found that the degree of conducting power is constant for the same kind of matter. We therefore speak of the specific conducting powers of bodies. There are such clear distinctions among the various kinds of matter in regard to this property, that bodies have been arranged in tables in the order of their conductivity. At the bottom of such a table, or among the best insulators, are glass, silk, wax, gutta serena, sulphur, spermaceti, oil of turpentine, &c. The metals have been always recognized as the best conductors. The liquids, with the exception of the oils, are good conductors. The latter fact explains the conducting powers of many bodies. The presence of moisture in the pores or upon the surface of a nonconductor, will give it a greater or less degree of conducting power. Without entering farther into this point, we may observe, that the various bodies, natural and artificial, take such a wide range in regard to specific conductivity, that it is common to speak of some bodies as perfect conductors, and of others as perfect insulators. Faraday, however, has hazarded the proposition, that all bodies, from the metals to gum-lac and the gases, conduct electricity in the same manner, though in very different degrees. We have not space here to show how powerfully this proposition is supported by experiment. Another circumstance that affects conduction is, the temperature of bodies. Well-dried glass, at common temperatures, is one of the best insulators; as its temperature increases, it receives a continually increasing conductive power, until, at a red heat, it conducts very well. Similar effects have been observed with other non-conducting bodies, solid and liquid. Temperature affects also the conducting powers of the metals. But it is remarkable that the effect in this case is contrary to that observed in the case of bad conductors; as the temperature of a metal increases, the conducting power diminishes. Another circumstance that affects conduction, is the physical state of bodies, as liquid or solid. It has been long known that, while water is a good conductor, ice is a very good insulator. A globe of ice has been, indeed, successfully employed in the electric machine, instead of the common cylinder or plate of glass. It has been stated further by Faraday, as a very general law, that bodies assume a conducting power during liquefaction, which they lose during congelation. The connection between this law and that of the influence of temperature last mentioned can hardly be doubted. Among the circumstances that affect conduction, we should not omit to notice the dimensions of the conductor and the intensity of the charge. The former circumstance will be taken up more properly in the article on **CURRENTS**; the latter may be thus briefly illustrated. The same body may act in a Voltaic circuit as a good conductor, and in a Thermo-electric circuit

CON

as a perfect insulator; the reason being this, that the intensity of the electricity evolved in the former case is much greater than that in the latter. For further information upon the subject of conduction, see CURRENTS. We have now to refer to the theory of conduction. In the older theoretical speculations upon electricity, conduction was regarded as the mere passage of the electric fluid or fluids; and the only agency ascribed to the conductor was, that of affording a passage to the electricity with more or less facility. An important addition was made to the theory of conduction by Delarive. He compared a continuous conductor to a series of indefinitely small conductors placed in a line and insulated from each other. If two oppositely charged bodies were put in contact with the extremities of this line, the first effect would be a system of inductive actions, by which every one of the small conductors would be electrified positively on the one side and negatively on the other. The *limiting* case of these inductive actions would be a system of discharges between contiguous conductors, and this would constitute the conduction of electricity through the whole series of small bodies. This view of conduction is evidently to a great extent hypothetical; and yet its importance cannot be questioned. Its value consists principally in this, that it explains the electric properties and actions of masses by the assumption of molecular properties and actions of the same kind. Faraday's *Theory of Conduction* might now be noticed, but it may be taken up much more satisfactorily in the article on INDUCTION. Certain general relations of the subject will be found also under ELECTRICITY.

Cone. A solid, whose base and every section parallel to it is a circle—more generally—any curve returning into itself—and which terminates in a point called the apex. The line from the apex to the centre of the base is called the *axis*; the *height* is the perpendicular on the base from the apex. The ordinary *right cone* has a circular base, to which the axis is perpendicular; the *oblique cone* has the axis inclined to the plane of the base. A *truncated cone* is the lower half of a cone cut by a plane parallel to the base. The cone is in fact a species of pyramid with an infinite number of infinitely small sides. The pyramid and cone depend on the same principles, and the same rules apply to them. The convex surface of the right cone is equal to half the product of the circumference of the base by the side of the cone—the side being a line drawn from the apex to any point of the circumference of the base. The solid content of the cone, like that of the pyramid, is one-third of that of a cylindrical solid of the same base and height, i.e. one-third of the product of the base by the height. The volume of a truncated cone is equal to the product of half the sum of its parallel ends by the perpendicular distance

CON

between them. Its convex surface is equal to the product of half the sum of the circumference of its ends, by its side.

Congelation, Line of Perpetual. See SNOW.

Congelation — Regelation. (See ICE.) The subject now referred to has recently assumed an importance that, until recently, did not belong to it. We shall discuss its peculiarities and physical bearings in detail under article ICE; but it is needful that a few general remarks be made here.—Congelation is the process by which liquids pass into the solid state, whether through effect of pressure or of the lowering of their temperature. The latter cause was, until recently, held as the chief cause of congelation, and the temperature of freezing water was taken therefore as an absolute point of temperature. But it is now very apparent that temperature is only one element. Gases can be pressed into the liquid form, and liquids into the solid form, by a combination of the two powers,—pressure and the lowering of temperature. Interesting relations between pressure and temperature, in reference to the freezing of water, were first brought out by Mr. James Thomson, C.E., Belfast. (See ICE.)—Furthermore, in reference to temperature alone, the existence of singular anomalies has long been known, and remained as a great puzzle; for instance, liquids often refused to solidify at the canonical temperature. Faraday has recently given forth some striking views on this whole subject:—"In all uniform bodies possessing cohesion, i. e., being either in the solid or the liquid state, particles which are surrounded by other particles having the like state with themselves, tend to preserve that state even though subject to variations of temperature, either of elevation or depression, which, if the particles were not so surrounded would cause them instantly to change their condition. As water is the substance in which regelation occurs, we will illustrate the principle by the phenomena which it presents. Water may be cooled many degrees below 32° Fahr., and yet retain its liquid state for, as far as we know, any length of time without solidification; yet, introduce a piece of the same chemical substance, ice, at a higher temperature, and the cold water freezes and becomes warm. It is certainly not the change of temperature which causes the freezing, for the ice introduced is warmer than the water. We assume that it is the difference in the condition of cohesion existing on the different sides of the changing particles which sets them free and causes the change. The cold water particles would willingly, as to temperature, have solidified without the ice, but were held fluid by the cohesion with them of other like fluid particles on all sides. In the other direction, Donny's experiments have taught us that the cohesion amongst the particles of water is so great, that it will support a column of the fluid four or more

CON

not high, when there is no other power to sustain it; or will cause it to resist conversion into the state of vapour at temperatures so much higher than its ordinary boiling, or condensing point, that explosion will occur when the continuity, and therefore the cohesion, is destroyed. The water may be exalted to the temperature of 270° Fahr., at the ordinary pressure of the atmosphere, and remain as water; but the introduction of the smallest particle of air or steam will cause it at once to burst into vapour, and at the same time its temperature falls.—This ability which water has to retain by cohesion its liquid state, refusing to solidify when below the freezing point, or to become vapour when above the boiling point, it has in common with many other substances."

Congruences. Two whole numbers, a and b , are said to be congruous to each other, with respect to the modulus m , when the difference $a - b$ is divisible without remainder by m . The relation of congruity is in itself so elementary and patent, that it has attracted the notice of mathematicians from the very infancy of the theory of numbers. Many important propositions in that theory are mere statements of congruity in particular cases—such as Fermat's theorem and Sir John Wilson's. But the subject has risen into new importance since the publication of Gauss's *Disquisitiones Arithmeticae*, a work in which many original results of an interesting and valuable kind were obtained by a thorough study of relations of congruity. Gauss proposed a new notation, which is very likely to prevail universally: he writes a *Congruence*, or a statement of congruity, between a and b , in a manner very similar to an equation between a and b , only with three lines instead of the two $=$. An immediate advantage derived from the notation is, that it reminds us of the close analogies which exist in fact between congruences and equations, and enables us to submit congruences to many transforming operations with the greatest ease, and without any danger of confusion. After Gauss, other mathematicians have been occupied with the subject, especially Poincot, Gallois, and Libri. They have found the properties of congruences to be of the utmost value in the higher parts of algebra and of the theory of numbers. But the most valuable result obtained from the study of congruences undoubtedly is, that by this means the theory of numbers has been saved from the reproach and inconvenience of an utter discontinuity of parts. A large part of the theory of numbers might now be thrown into a form as systematic and as closely reasoned as the theory of equations, and in many points bearing a close resemblance to it. The best connected exposition of the subject will be found in Serret's *Algebre Supérieure*, where three chapters (23, 24, 25) are devoted to it. The English student of the higher Algebra would do well to master this important work.

CON

Conic Sections. Four curves formed by sections of the right circular cone made by a plane in different directions. If the plane cutting the cone be parallel to the base the curve will be a circle. If it cut it slant across, cutting the two sides, the curve will be an ellipse. If it be parallel to the side of the cone it will be a parabola, and any other section will be a hyperbola, if it be inclined to the axis at a less angle than the side of the cone. If two cones were set one on the top of the other, so that the one is just a continuation of the other through the apex, a plane which by section would make a hyperbola would cut the second cone as well as the first, though none of the other planes would. There are thus two equal branches of the hyperbola belonging to the two cones respectively.

Other methods of describing the conic sections on a plane are frequently given. From that already specified the name comes. The circle is described by a compass. The method of describing the ellipse, parabola, and hyperbola, is mentioned elsewhere. The general equation which represents all of the conic sections is $y^2 = mx + nx^2$, in which, for the parabola $n = 0$, for the ellipse $m = \frac{2b^2}{a}$ and $n = -\frac{b^2}{a^2}$, for the circle $m = 2a$; $n = -1$, (b and a being equal), and for the hyperbola $m = \frac{2b^2}{a}$ and $n = \frac{b^2}{a^2}$. See ELLIPSE, HYPERBOLA, PARABOLA.

Conjunction. When two or more bodies are seen very nearly at the same point of the sky, we say that they are in conjunction. Conjunctions are *geocentric* or *heliocentric*, i.e. we do see the bodies together or nearly so, in the former case; and in the latter we would see them so if we observed from the sun. It is always necessary to remember that our observations at the surface of the earth require to be reduced to what they would be at the centre. This is customary in order to secure a method of marking the exact times of conjunction, and that every observer may make his observations, at once useful to every other. The conjunctions most frequently mentioned are of the planets and sun. When the sun and a planet are in the same direction from us, they are in conjunction. The terms *inferior* and *superior* conjunction refer to this. Some of the planetary orbits are within the earth's orbit. These are called *inferior* planets, such as Mercury and Venus. Now they will clearly be in conjunction with the sun twice: 1st. When they are between us and the sun; and 2d. When the sun comes between us and them. The former is said to be *inferior conjunction*, the latter *superior conjunction*. The *superior* planets, whose orbits lie entirely without that of the earth, such as Jupiter, never come between us and the sun, and therefore there is no *inferior conjunction* with them. When, however, we come between

CON

them and the sun, they are said to be in *opposition* to the sun.—*Grand conjunctions* are said to be those where several stars or planets were found together, or near one another. Thus, on March 17th, 1725, Mercury, Venus, Mars, and Jupiter, were all to be seen by the same telescope at the same time, without altering its direction. The Chinese history records a grand conjunction, in the reign of the Emperor Tehuen-hiu (2514-2486 B.C.), of five of the planets. Astronomers calculate that such a conjunction actually took place in 2461 B.C., when Saturn, Jupiter, Mars, Mercury, and the Moon, were within 14° of one another. The moon could, however, scarce be mistaken for a planet, and in all likelihood the grand conjunction is merely a conjunction of three or four planets, of much more recent date, magnified into five for the glory of the Celestial Empire.

Connecting Rod. A rod in a machine intended to transfer motion from the place of its generation to a point where it is required. It is attached to one point which moves directly, and to another point intended to move. The motion of the former, is by it communicated to the latter. There are different forms of it, according to the kind of motion originally produced and the kind which may be required in the point to which it is fastened. See *Willis's Principles of Mechanism*.

Conoid. A solid formed by the revolution of a conic section round its axis. The sphere, the paraboloid, the ellipsoid, and the hyperboloid, are the various conoids.

Conservation of Force. See Article **FORCE**.

Constellation. The first appearance of the celestial vault gives us no idea of order or uniformity. The stars seemed strewed up and down; and we should not expect, therefore, in this irregularity to find them keep their relative positions. They do so, however—with a few exceptions (planets)—and hence the vault, night after night, presents the same appearance to the spectator. This makes it possible for the observer to watch all the phenomena of any one star. If the stars were visible in the day-time, he might follow it round and round its circuit. But the sun blots out the stars in the morning, and the night restores them to the sky. All this time the stars have been moving, and are, therefore, not found in the same place in which he left them in the morning. How, then, shall he re-discover his lost star? In this difficulty, he has recourse to the *grouping* of the stars. He notices three or four which have a peculiar configuration—which stand at certain distances—and which appear with certain lustres. These are different in their total appearance, from any other equal number in the sky. He recognizes the group then at night, and each star by its individual position in the group. This grouping, arbitrary for each observer, would be sufficient, if he could remember it distinctly, and if he confined his ob-

CON

servations entirely to himself. But he wishes to communicate what he observes, and to exchange communications. In order that he may do so, a *uniform* system of grouping is adopted, and this system is also intended to assist the memory. Unfortunately, this last end has been very inadequately attained. The groups are called **CONSTELLATIONS**.—The system of grouping universally employed bases principally upon the Grecian mythology. Figures of men and of beasts are supposed to be outlined in the sky by various groups of stars, and mythological names are assigned to them. The stars in each constellation are named by the letters of the Greek alphabet (α , β , γ , &c.), in the order of their brilliancy, and when there are more stars than there are letters, the ordinary numerals follow in succession. The division of the stars into constellations is very ancient. It is mentioned in Job, and in Hesiod and Homer. Aratus made a formal arrangement; but the first generally received was that of Ptolemy, in which the heavens, *visible to him*, were divided into 48 constellations—12 in the zodiac, 21 in the northern, and 15 in the southern hemisphere; Hevelius added 12 new constellations, Halley 8, Bayer 12, La Caille 15, and different other astronomers 12 more. The complete number is thus 107. The following is a list of the constellations:—

CONSTELLATIONS OF PTOLEMY.

Northern.

1. Ursa Minor (the Little Bear).
2. Ursa Major (the Great Bear).
3. Draco (the Dragon).
4. Cepheus.
5. Bootes (the Ox Driver).
6. Corona Borealis (the Northern Crown).
7. Hercules.
8. Lyra (the Lyre).
9. Cygnus (the Swan).
10. Cassiopeia.
11. Perseus.
12. Auriga (the Charioteer).
13. Ophiuchus (the Serpent Bearer).
14. Serpens (the Serpent).
15. Sagitta (the Arrow).
16. Aquila and Antinous (the Eagle and Antinous).
17. Delphinus (the Dolphin).
18. Equuleus (the Little Horse).
19. Pegasus.
20. Andromeda.
21. Triangulus (the Triangle).

ZODIACAL CONSTELLATIONS.

22. Aries (the Ram).
23. Taurus (the Bull).
24. Gemini (the Twins).
25. Cancer (the Crab).
26. Leo (the Lion).
27. Virgo (the Virgin).
28. Libra (the Balance).
29. Scorpio (the Scorpion).
30. Sagittarius (the Archer).
31. Capricornus (the Goat-horned).
32. Aquarius (the Water Carrier).
33. Pisces (the Fishes).

SOUTHERN CONSTELLATIONS.

34. Cetus (the Whale).
35. Orion.
36. Eridanus.
37. Lepus (the Hare).
38. Canis (the Dog).

CON

39. Procyon.
40. Argo.
41. Hydra.
42. Crater (the Goblet).
43. Corvus (the Crow).
44. Centaurus (the Centaur).
45. Lupus (the Wolf).
46. Ara (the Altar).
47. Corona Australis (the Southern Crown).
48. Piscis Australis (the Southern Fish).

MODERN CONSTELLATIONS.

I. Added by Hevelius.

1. Antinova.
2. Maenetus.
3. Canes Venatici (the Greyhounds).
4. Asterion and Chara (the Giraffe).
5. Cerberus.
6. Coma Berenices (Berenice's Hair).
7. The Lizard.
8. The Lynx.
9. Sobieski's Shield.
10. The Sextant of Urania.
11. The Little Triangle.
12. Leo Minor (the Lesser Lion).

II. SOUTHERN CONSTELLATIONS.

Added by Halley.

1. Columba (the Dove).
2. Charles's Oak.
3. Grus (the Crane).
4. The Phoenix.
5. Pavo (the Peacock).
6. The Indian Bird.
7. Musca (the Bee).
8. The Chameleon.

III. SOUTHERN CONSTELLATIONS.

Added by Bayer.

1. The Indian.
2. The Crane.
3. The Phoenix.
4. The Bee.
5. The Southern Triangle.
6. The Bird of Paradise.
7. The Peacock.
8. The Toucan.
9. The Male Hydra.
10. The Dorado.
11. The Flying Fish.
12. The Chameleon.

SOUTHERN CONSTELLATIONS.

Added by La Caille.

1. The Sculptor's Workshop.
2. The Chemical Furnace.
3. The Astronomical Clock.
4. The Rhomboidal Net.
5. The Graving Tool.
6. The Painter's Easel.
7. The Compass.
8. The Air Pump.
9. The Octant.
10. The Square and Rule.
11. The Telescope.
12. The Microscope.
13. The Fabulous Mountain.
14. The Great and Little Cloud.
15. The Cross.

THE REMAINING MODERN CONSTELLATIONS.

Added at different times.

- The Reindeer.
- The Hermit.
- The Farmer.
- Pomiatowski's Hawk.
- Frederic's Honour.
- The Sceptre of Brandenburg.
- Herschell's Telescope.
- The Balloon.
- The Quadrant.
- The Cat.
- The Log.
- George's Harp.

CON

There are several maps of the stars, in which the constellations are usually traced out as on the celestial globe. Flamsteed's *Celestial Atlas*, London, 1729, and Bode's, Berlin, 1805, are the best. There are several excellent maps published by the Society for the Diffusion of Useful Knowledge.—The arrangement of the constellations as they stand is not very natural. It is still, however, employed for the purposes of reference—and as the point of first importance in such matters is the uniformity of the standard, it is not necessary to disturb it. The Chinese and Japanese, indeed, depart from this uniformity, but their astronomy has not yet been very extensively introduced into Europe.—In consequence, however, of the slight esteem in which our system of constellating the stars has been held, various attempts, sufficiently amusing, have been made to change it. Some pious astronomers, grievously scandalized at the employment of the names of fabulous divinities by Christian men, gave a spiritual sense, where it was possible—making Aries stand for the ram that was substituted in the room of Isaac—and others, as the venerable Bede, finding this method rather unsatisfactory, cut the knot, and placed the twelve Apostles triumphantly in the twelve zodiacal signs. This reformation was carried over the whole of the constellations, and all the profane of the old times were swept away.—Weigelius of Jena adopted another plan. He taught heraldry by the stars, substituting for the old constellations the arms of the various princes of Europe, and the insignia of the different crafts. Thus Ursa Major, being a quadruped, became the elephant in the Danish arms; and the Pleiades were metamorphosed into an Abacus, which he would have to be the symbol of merchants. Those divisions have passed away, and the reign of Orion and Bootes still endures.

Convection. That property of liquids or gases by which, when in a free state, constant motion is secured to them, through changes of temperature. The term is employed chiefly in connection with the theory of dew. When a windy night arises, the deposition is said to be prevented by convection. This is not properly convection, but from its effects being analogous, it is so termed. The air as it cools is carried away and replaced by fresh air coming from or passing to those quarters of the earth where the sun is yet shining. When a mountain intervenes, too, the hotter air above intermingles with the cooler air below, by force of the current, and is carried over, so intermingled. Again, the cooling of air, and the deposition of dew upon hill tops is prevented by convection. Before there can be an approach to such a deposition, the temperature must become very low, from the lowness of the dew point upon hill tops. When it becomes so, the air is considerably heavier than that, in lower strata, farther removed from the actual, irregular surface of the earth. It commences, therefore, to slip down

the hill side, and thus lighter air comes to take its place, is again cooled, and again creeps down before depositing any or much dew. The heat which these successive strata give to the earth prevents its cooling so rapidly, and they themselves, on whose cooling the dew depends, are thus carried away before they can cool. It is only at the plane surface of the earth, or in valleys, where they cannot take place, that dew is plentifully formed.—Convection again assists the formation of dew by carrying up the air from which part of its vapours has just been condensed, and which so becomes light by the disengagement of the latent heat of its vapour. Air not so heated and with all its vapour falls down, and the process recommences. The difference between this and the last case is, that the dew is formed here before the air is allowed to move. Liquids are generally heated by convection—when heat is applied from below. Thus water, held nearly vertical and boiled in a test tube, to the bottom of which a spirit lamp is applied, scarce at all conducts the heat. If, therefore, the weight of hot and cold water were the same, the layers below might be at a very high temperature and those above in their ordinary condition. But the heated water being lighter, ascends, and lets cold water down to the heated place, which in its turn reascends, and so continues the process. Some liquids, such as mercury, are not bad conductors, but in the great majority of instances it would be very difficult to heat liquids thoroughly but for the property of convection. It is with the utmost difficulty that any conduction is detected in water. If we place a lamp in a vessel which floats in water, the vessel itself freely conducting heat, the layers below will be long before they take a heat sensible to the thermometer, and even then the heat seems conducted down along the side of the glass, or other containing vessel, rather than through the water.

Convergent. When a series of magnitudes is such that, by taking the sum of as great a number of them as we choose, we do not arrive at a result above a certain finite quantity, the series is said to be convergent. The name originates in the fact that the terms of such a series must successively decrease, the second being less than the first, the third than the second, and so on.—The same term is applied in physics to the lines of rays which, originating at different points, go on constantly approaching one another, so that if they be lengthened out sufficiently they will meet at a point. See LENS and MIRROR.

Convex. See CONCAVE.

Co-ordinates. The method of co-ordinates is due to Des Cartes, and is perhaps his most valuable contribution to mathematical science. It first enabled us to indicate *quality* by the ordinary signs of *quantity*, and to compare different qualities quite as accurately as we had been wont to compare quantities. We can only

give a very meagre outline of it. Suppose that we have a curve, such as $b_1 b_2 \dots b_6$ upon a plane surface, on whose plane two lines at right angles to one another, $X X'$ and $Y Y'$, are drawn. Then the position of any point in the

plane will be quite determined if we know its distance from the lines $Y Y'$ and $X X'$. Thus, if we know the distance of a point from the line $X X'$, we will evidently cut off a line $O K$ equal to that distance, and through it draw a line parallel to $X X'$. Any point in this line will answer the conditions of the question, for any such point will be at the specified perpendicular distance from $X X'$. Again, if we know the distance from $Y Y'$, a similar line through a_1 , ($O a_1$ being equal to that distance) will contain all the points that can answer to the conditions. Since then the point specified must be in each of those two lines, it can only be in that point where the two lines meet. But it will be said, are there not two lines each of which may be the locus of points at given distances from $X X'$, $Y Y'$? (the *axes* of co-ordinates.) Thus may there not be four points, the four marked b_1 in the figure, each answering to the specification fully? According to geometrical principles undoubtedly yes, but the algebraical extension of this method enables us to specify which of these four possible points we mean in any case. This introduces us to the first glimpse of an estimation of quality. If the measurement of the distance from the line $Y Y'$ is to proceed along $X' X$ from O towards the right, the distance is considered as positive and marked by a quantity representing its absolute amount, with the sign $+$. Similarly, if we are to measure from O , along $O X'$ towards the left, we should indicate it by prefixing the sign $-$, to the absolute quantity representing its length. And again, if we are to measure the distance from $X X'$, upwards from O along $Y Y'$, we should have $+y$; and if in the opposite direction, $-y$. Suppose then that we have x and y both positive, we should have the point marked 1. If we have $+y$ and $-x$, the point marked 2; $-x$ and $-y$, the point marked 3; $-y$ and $+x$, the point marked 4; supposing always that $O a_1$ represents x , and $O K$ represents y .—The axes, or lines of reference, need not be at right angles but oblique in any way to each other, and in that case the distance would most

properly be estimated, not by the perpendiculars from the point upon the lines of the axes, but by the lengths of lines from the given point parallel to the one axis and intercepted against the other. When we have the position of a curve with respect to any given axes, and the position of a new set of axes, with regard to the old ones,—given, it is plain that methods may be discovered for determining the position of the curve, with respect to this new set. The problem which proposes this is that of the transformation of co-ordinates. The various formulae which enable us to solve it are given in every work on analytical geometry.—The reader will be able to comprehend what is meant by an equation to a curve from this. It is, in fact, an algebraical formula which expresses the value of y in terms of the value of x . If now any value whatever be given to x , a corresponding value will be found for y , and thus there will be a point in the curve found. Thus, suppose that Oa_1 is given as a value of x in any equation, and that by solving the equation we find a_1b_1 to be the value of y , then the point of the curve which corresponds to those values will be very readily found by drawing a_1b_1 parallel to OY , and making it equal to y , as just found. The point b_1 will be a point in the curve. Suppose now that for the successive values $Oa_2, Oa_3, Oa_4, Oa_5, Oa_6$, of x there be found corresponding values $a_2b_2, a_3b_3, a_4b_4, a_5b_5, a_6b_6$ for y , the points b_2, b_3, b_4, b_5, b_6 will be points of the curve. If the number of the values of Oa thus taken be almost infinite, so that the distances between two successive points a , become indefinitely small, those between two successive points b , will become so likewise, and by joining them we shall obtain a polygonal figure very closely resembling the curve which the equation indicates. The nearer these points come to one another, the closer the resemblance. It will be quite manifest that in this way a representation of all qualities of the curve may be made in the original equation. When it has risen to its highest point, we shall get the greatest possible value of y to match. When it cuts the line of the axis, y will be equal to 0; when it is parallel to the axis of x , two very near ordinates y, y' , will be equal; when the curve terminates in one direction there will be no value of y for values of x beyond a given point—when there are two values of y for one of x , as a_5b_5 for Oa_5 , the curve has returned upon itself, and so on. Thus every quality of the curve can be represented in the equation, through the uniform reference to co-ordinates.—What are called co-ordinates of three dimensions are three lines, each of which is perpendicular to the plane of the other two—in rectangular co-ordinates. In oblique co-ordinates, the three lines are any three not in one plane. By means of such co-ordinates we can refer curves which are not entirely in one plane, the lines through

which we make reference being parallel to the axes as before. The methods of transformation of co-ordinates of three dimensions are a little more complicated than those where there are only two. The three ordinates are usually marked x, y, z , the signs $+$ and $-$ being prefixed according as the reference is to the one or other half of the complete axis. With merely x, y, z specified without regard to sign, there could be 2^3 , (2^3 in the last instance) or 8 points, answering to the specification.—The method of co-ordinates is much used for resolving forces in mechanics and for finding the value of the resultant of a number of them. Each force is resolved into three others, one along each axis of co-ordinates, and the algebraical sum of all these components for each axis is taken, the resulting three being compounded into one force, which is the complete resultant. Where all the forces are in one plane, we employ co-ordinates of two dimensions.

Copernican System. The correct description of the general character of the planetary motions is termed the Copernican System; for the sufficient reason that the planetary character of the Earth was first discovered by the immortal Copernicus. It is often difficult, when one observes a change of direction in external bodies, to dis sever their *real* from their *apparent* motion—the latter arising from change of place on the observer's part. The planets, for instance, seem to pass through various and irregular courses in the sky. How much of this apparent change of place is real?—how much owing to change of place on our part? The ancient world conceived the Earth stable, and therefore accounted all apparent external motion to be *real*: hence the complexity of their Astronomies. Copernicus determined otherwise. He asserted that the rotation of the Earth on an axis, explains the apparent diurnal revolution of the entire celestial vault; and, by the still more venturous proposition, that the Earth is a planet, revolving annually in an orbit around the Sun, he removed all primary difficulties from Astronomy. His views, however, were *hypothetical*. He could not demonstrate the fact, either of the annual *revolution* or of the Earth's *rotation*. The former was not exhibited as a *fact* until Bradley discovered the *Aberration of Light*; and the demonstration of the latter, as a *fact*, we owe quite recently to the Frenchman, Foucault. (Compare EARTH, *rotation of*.) It is quite an error to suppose that the Copernican Theory, or anything akin to it, had been foreshadowed by the Greek, Philolaus. The only real anticipation was by Aristarchus of Samos, whose writings Copernicus did not know. For details, see SOLAR SYSTEM.

Corona. See CROWNS.

Corona Australis (*the Southern Crown*). A constellation of the southern hemisphere. It contains no very bright stars.

Corona Borealis (*the Northern Crown*).

Its companion constellation in the northern hemisphere. Neither does it contain any above the third magnitude.

Corpuscular Theory. See MOLECULAR.

Corrections. What is termed the *Theory of Corrections*, has come to be of vital importance in all the exact sciences depending on the use of instruments and measurements. An instrument, however skilfully made, cannot pretend to the attribute of absolute exactness; but as the highest exactness is required, the modern observer is, therefore, never satisfied with the best instrument with which art can furnish him. On receiving it, it is his first duty to suppose *that it is all wrong, in every part*. And his next is, by carefully comparing it either with another instrument already tested, or with certain known unchanging facts in Nature, to detect *the nature and amount of its errors*. These obtained, the observer *corrects*, or allows for them, in every individual observation; and only, after effecting these CORRECTIONS, does he consider his act of observation complete.—It would be impossible within our space to survey in detail a subject so extensive as this. Suffice it to advert to a few leading points. I. An instrument may be faulty in *position* merely. For instance, the Transit telescope of the Astronomer may not be quite in the *meridian*; its *axis* may not be perfectly *level*; and its central vertical wire may not be in the optical axis of the tube, i.e., it may be out in *collimation*. Each of these errors must affect every observation; so that as they cannot be entirely removed mechanically, their amount must be measured, and their effect on the observed transit of every star, *corrected for*. It is the same with all other instruments. II. Again, the *structure* of the instrument may be such, that no one part of it, taken by itself, can be made absolutely exact. For instance, to subserve the purposes of an astronomical circle, the circle used should be a perfect circle, and its pivots absolute cylinders. The mechanic cannot realize such a requisition—such perfection being, for the most part, *ideal*; but his art is, to contrive the instrument so, that *in virtue of its structure*, the various errors of its separate parts *compensate each other*. This is the secret of the only possible *mechanical CORRECTION*. III. Errors of construction will remain however, which cannot be compensated. And these, the observer must ascertain and correct for. Of such sort, for example, are the false zero point of a thermometer, or inequalities of the bore of its tube. It is astonishing how far solicitude and skill may go to effect correction, for even complex and apparently unmanageable mechanical errors. For instance, that most faulty meridian circle at the Cape of Good Hope—a circle in which literally no part was right—became, in the hands of the late Mr. Henderson, the means of first detecting the *parallax* of a Fixed Star. Nevertheless it needed the rare skill of that eminent Scottish observer—one of the foremost in Europe—to deal

with the comparatively intractable case. To raise his instrument above such defects, is the pride of the great mechanician.

Correlation of Forces. See FORCE.

Couples. The theory of couples, introduced by Poinsot, is now universally accepted by writers on mechanics. We shall require, therefore, to show what it is, and what it means.

When two parallel forces act at the extremities of a rigid rod, if their directions be the same, they may be replaced according to the theory of parallel forces, by a force equal to their sum and in a line parallel to their lines of action, acting at a point *between* them. When they act in opposite directions, they may be replaced by one equal to their difference, acting in a line parallel to their lines of action, in the direction of the greatest, but *beyond* the points where they are applied. The nearer the two forces, in this latter case, are to equality, the farther does the point of application of the resultant move outwards. When they become equal, the resultant becomes zero, and the point of application of the resultant is placed at an infinite distance from the points of application of the original forces. We have, therefore, in this *limiting* case, a zero force, with an infinite lever arm for the resultant, that is, the result that we obtain indicates nothing but that we must seek for some other method to arrive at one. In fact, what action will such a pair of forces exert? Manifestly, they will turn the rigid rod round. Suppose, for example, two ropes attached to the bows and stem of a ship, and pulled in opposite but parallel directions with equal strength. The ship will not move forward in the one way or in the other. The relation in which it stands to the two directions is quite the same over the whole. The relation in which the middle point stands to them is perfectly so. A point nearer the bows will be influenced rather by the nearest force, and a similar point near the stem by that opposite which is nearest it. There will thus be a rotation of the system round the middle point or pivot, all the other points moving in circles about it. The effect of a couple, therefore, is to produce *rotation*.—A couple, then, producing essentially *rotation* cannot be replaced by one force (or by any number of forces which may be replaced by one), which produces *translation*. When we have, therefore, to consider the motions which a set of forces impress on a body, or the conditions of its equilibrium when they are applied to it, we have to keep these two things perfectly distinct. We obtain thus, through the Theory of Couples, this answer in those cases:—The motions resulting will be such a motion of translation, along with such another motion of rotation; or such an expression for the total force inducing translation, and such another for that inducing rotation must be each equal to zero, in order that there may be equilibrium.—Where there is left in a system a force and a couple, if the force be not perpendicular in its line of action

CBO

to the plane in which the forces of the couple are situated, it may be convenient to reduce it to two forces—not, however, acting at one point. It is not possible, in any case where a couple and a force not in its plane are found, to reduce them to a single couple or to a single force. Where the resulting force is in the plane of the couple, the reduction to a single force is always possible, and, therefore, since a force and a couple are inconvertible, they cannot be reduced to a single couple.—The line which joins the two points of application of the parallel forces in a couple is called the *lever arm* of the couple. What is called the *moment* is the product of the perpendicular distance between the two lines of force, and either force. The axis is a line drawn perpendicular to the plane of the couple, and proportional in magnitude to the moment. It is immaterial where the axis be placed, as regards the forces of the couple, for any couple in the same plane, and having the same moment as another, is equivalent to it. Hence two parallel axes of equal length represent equivalent couples, and, if in opposite directions, destroy one another.—The axis is always used instead of the couple. When we wish to ascertain the conjoint effect of two couples, we treat the two axes as we would two forces, with this difference, that we can always transport either axis parallel to itself, and so obtain a resultant axis, whose length represents the moment of the resultant couple, and whose direction is perpendicular to its plane.—The three technical equations of equilibrium which express that the resultant couple must in that case be zero, are given under EQUILIBRIUM.—An investigation of the two propositions fundamental in the Theory of Couples that we have indicated—which the student perhaps, keeping in mind the proposition of the parallelogram of forces, may discover for himself—will be found in *Delaunay's Cours de Mécanique*, vol. i., *Pratt's Mechanics*.

Co-Variables. See POLYNOME.

Crowns: Corona. When the sky is covered with light clouds, we often see a coloured circle in which red predominates, surrounding the moon or the sun,—its diameter comprising only a few degrees. At other times several concentric rings are observed, separated by intervals in which green predominates: these are *Crowns* or *Corona*. The corona is not complete unless there are several series of concentric circles. The circle nearest the sun is of a deep blue; the second circle is white; and the third red, which terminates the first series. In the second series the succession of colours is purple, blue, green, pale yellow, and red. The cause of the phenomena is **DIFFRACTION**. See also ANTHELIA.

Cryophorus. A word signifying a carrier of cold. It is the name of a very pretty little instrument illustrative of the principles of evaporation, whose form is given in the figure. It consists merely of a tube with two bulbs, B and C. In

CRY

constructing the instrument, one of the bulbs, as C, is at first open, and by it water is poured into the vessel till the other bulb stands about one-third full. This water is then boiled, and

the whole instrument fills rapidly with steam. When all the air is expelled by the steam, and only a clear jet of steam issues from the orifice, it is closed by the blowpipe, and the tube thus hermetically sealed. The instrument is then allowed to cool down with its end B downwards. The water gradually flows back to it, and a very small quantity of vapour of water is left in the rest of the instrument. If now C be surrounded with any freezing mixture, or in any way be subjected to a degree of local cold below 32° Fahr., the water in the bulb B will very soon freeze, and it is this phenomenon which the instrument is intended to effect.

The phenomenon is explained thus. Every quantity of water gives off vapour, and if it pass into a space where the temperature is kept at a certain point, and be not allowed to pass off from that space and dissipate, there will be a certain amount of vapour and no more given off. This amount increases with the increase of temperature. Now suppose the temperature suddenly lowered. The space can no longer hold so much vapour, and the superabundant quantity will be condensed. Now there is a certain amount of heat latent in every quantity of vapour, and when condensation takes place this heat is liberated. See HEAT, LATENT. The temperature of the space where condensation has occurred will therefore—the moment after all the vapour superabundant has been condensed be raised so that it is capable of receiving more vapour which the water will immediately give off. If the cold be applied again, the vapour will be recondensed, new heat given off, new vapour formed and again condensed. In the cryophorus this process goes on, when a freezing mixture, or any method of supplying local cold, is applied to the bulb C. The vapour in C is condensed. This condensation liberates heat, giving capacity in C for more vapour, supplied immediately from B, and recondensed by the continued application of cold. That the condensation of vapour then, liberates heat, is the principle illustrated, next to the theory of states of saturation of vapour, corresponding to temperature, in the bulb C. The condensed vapour does give off heat, because in being formed it takes in latent heat. Thus to send off vapour at any temperature from water, we must use much more heat than in raising the water to the same temperature, without permitting vapour. A quantity of heat not sensible

to the thermometer is essential to the existence of a body in a vaporous state. When, therefore, the bulb, c, suddenly raised in temperature by the condensation of vapour into water, demands to obtain more vapour from the water in c, the heat for this new vapour must be obtained. It is got from the water in B, and the process goes on so rapidly in ordinary cases that the air without is not able to supply heat as rapidly to B, and the water inside, as it thus loses it. The temperature is thus gradually lowered, and ice is formed.—The principle of the cryophorus explains many of the most interesting phenomena of meteorology. We shall see that the formation of dew, and fogs, and mists, is very closely connected with it. The rapid formation of the ice, and the quantity formed in a given time, may be taken as rough measures of the power of the freezing mixtures of which we treat. The phenomenon is in any case interesting, and it is easily shown not at all to depend upon actual conduction or radiation of cold (or inverse radiation of heat), by placing a little water quite near the cryophorus—which is not affected almost at all sensibly to the thermometer by this conduction or radiation.

Cube. A solid with six faces, each of which is a square, each square being therefore parallel to the one opposite it. It is a frequent form for crystals. Those that assume it are not doubly refractive along any line of ray. It was a celebrated problem in the ancient geometry to find a cube which shall be double of a given one. In fact it was required to find a cube root of 2 by geometry. Modern researches have shown that this, along with the two other celebrated problems of the trisection of an angle and the quadrature of a circle, cannot be solved by pure geometry. In arithmetic, the cube of a number is the product obtained by multiplying it three times by itself; thus, $5 \times 5 \times 5 = 125$. Conversely the cube root is such a number as when multiplied 3 times by itself will produce the given number. Thus 5 is the cube root of 125, and 125 the cube of 5. See **Roots**.

Culmination of a star:—the moment at which the star passes the meridian, and is therefore highest in its diurnal revolution. The culminating point of a great circle is that where it intersects the meridian.

Cupola. A hollow spherical body in the shape of a reversed cup, which surmounts a circular edifice. It is the same as the dome, only that the former name applies more generally to the inner, and the latter to the outer surface. See **DOMES**.

Currents, Atmospheric. See **WINDS**.

Currents, Electric. Reserving a more detailed exposition of the subject of currents for the article on **ELECTRODYNAMICS**, we may give here a brief introduction to the subject, and add a few statements in regard to the laws and the nature of currents, that could not so properly be

made in the article referred to. We have the example of an instantaneous current in the discharge of the Leyden Phial or Battery, or other similar arrangement. According to the common form of the experiment of discharge, no effect is observed except at that part of the circuit where the discharging rod is separated from the coating, or more generally where the conducting circuit between the coatings is interrupted, so as to give rise to a spark or other phenomena of disruptive discharge. But we know that the conducting part of the circuit, is also in a peculiar electric state at the instant of discharge; a state essentially distinct both from the natural condition of the body, and from the condition of mere charge or electric tension. In these circumstances, when the opposite electricities are—according to the common modes of statement—moving through the circuit, uniting, and mutually neutralizing each other, the circuit is said to be traversed by an electric current. To derive from this illustration an instance of the more common and important kind of current—that is, the continuous—we have only to suppose that one of the coatings of the Phial is connected with a continual source of electricity, while the other coating is uninsulated, or connected with a source of opposite electricity. In these circumstances the discharge condition will be sustained in the circuit that unites the coatings; new charges being supplied as those formerly evolved are neutralized: in other terms, the circuit will be traversed by a continuous current. The discharge of the Leyden Phial has been employed in illustration, for the purpose of connecting in a simple way the subject of currents with that of statical electricity. But the most common type of the current in connection with its source is the Galvanic Battery, or the simple Galvanic Circle. Two plates, one of zinc the other of copper, are partially immersed near each other in dilute sulphuric acid; and their unsubmerged parts are connected by a wire. It is found that the wire is traversed by a current, as if the copper plate were a source of positive electricity, and the zinc of negative. It is important to remember that the direction which is conventionally ascribed by scientific men to the current, is in the above instance from the copper to the zinc, through the wire. In general, what is called the direction of the current is the direction in which the positive electricity appears to move in the circuit. Having obtained a simple type of the current, we may consider some of its effects, confining ourselves to those by which the current itself is most clearly manifested, and by the observation of which it is usually detected and measured. One of the earliest known actions of electricity in motion is the calorific, of which we have an instance in the incandescence of a fine wire by the discharge of a Leyden Battery through it. Similar effects, rising in intensity to the fusion and brilliant

combustion of metallic circuits, are produced by continuous currents of sufficient power. In general, the temperature of a circuit is raised by the passage of electricity through it. This thermic influence upon the circuit has been employed in several ways for the measurement of the current. In Delarive's *Rheometer*, or current-measurer, for example, which was the first invented instrument of this kind, the current is detected, and its power approximately determined, by the temporary extension of a fine metallic wire forming part of the circuit; the extension being due to a rise of temperature. In another and more sensible instrument, the fine wire traverses the bulb of an air-thermoscope, and the effect observed is the expansion of the air by the heat communicated to it from the wire. Instruments of this kind were to a great extent useless for the purpose of measurement until those laws had been determined, by which the intensity of the current is connected with the quantity of heat evolved by it in the circuit. And though we now have this knowledge through the recent discoveries of Mr. Joule, the instruments referred to are of little or no use, compared with those to be afterwards mentioned. Another class of effects of electricity in action may be generally termed the electro-magnetic. A circuit that is traversed by a current is found to exert certain magneto-inductive and mechanical actions upon magnets and magnetic bodies in its neighbourhood. The laws of these actions, and more especially of the mechanical, have been determined with great accuracy; and they have given to physical science one of its most valuable instruments, the Galvanic Multiplier. See GALVANOMETER. A third class of effects of the current are the chemical. When certain liquids form part of the circuit, they are chemically decomposed, and the elements are set free, in the simplest cases, at those parts of the liquid where the current enters and leaves it. By the labours of Becquerel and others, and especially by the beautiful researches of Faraday, the laws of this class of actions have been very fully investigated, and they have supplied a rheometric instrument in his Volta-Electrometer, that leaves nothing to be desired in regard to the measurement of currents which have a certain intensity. These brief remarks on the effects of electricity in action are sufficient for our present purpose; which is to give some indications, however slight, as to the several ways in which the existence of currents is usually detected and their strength estimated. Having considered some of the effects, we may now look with equal brevity to the sources. A current may be obtained in general by the discharge of statical electricity by whatever means excited. But the more important kinds of current are derived from sources which evolve statical electricity of excessively feeble tension. In the present state

of science, the most valuable source and that most commonly employed in experiment is chemical action, exemplified in the common forms of the Galvanic Battery. Heat is also an important source when peculiarly distributed in heterogeneous metallic circuits, as will be shown under THERMO-ELECTRICITY. A third source of currents is found in the magnetic forces, combined with certain movements of the conducting circuit in the field of force. The evolution of electricity in this way is well exemplified in Faraday's magneto-electric machine. The sources and effects of electricity will fall under our special consideration in other places, so that we need not dwell upon them further at present. An essential character of the current is the constancy of its powers at all parts of the circuit. Thus, it has been long known that all equal lengths of the circuit, when acting upon similar magnets in similar positions and at the same distances, produce equal deviations. A similar law holds in regard to electro-chemical decompositions. If several processes of decomposition go on at different parts of the circuit, the power expended is the same for each; so that, if the compounds be the same, the quantities of the elements evolved in the several processes are equal. The truth of the general law has appeared to be more than questionable in regard to the calorific power of the current, as we shall see afterwards; but the law as it stands is highly important. The laws of the Intensity of Currents have been investigated with much diligence and success. Sir H. Davy was the first to attempt the investigation; and besides obtaining other important results, he laid down these two laws, that the intensity of a galvanic current varies inversely as the length of the circuit, and directly as its section, supposing the source to be of constant energy. These laws have been extended, since his time, to liquid circuits, and to Thermo-electric currents. Pouillet discovered that the first law, as stated by Davy, required an experimental correction; and the correction when made, gave this beautiful result, that the Pile itself affects the Intensity of the current, not merely by its action as a source, but also by an action as part of the entire circuit in transmitting the electricity, and that the latter action is introduced into Davy's law by attributing to the Pile a constant effective length for all conditions of the rest of the circuit. The importance of the laws of intensity may be inferred from this consideration, that they indicate some of the conditions which are essential to the development of currents, and to their development with a greater or less power. Closely connected with this subject is that of Conductibility. The specific conducting powers of the metals have been very diligently investigated by several philosophers, and according to various methods. Passing by the older methods of Davy, Pouillet, and others, we may mention one suggested by Faraday.

When conductors move in a certain way in the neighbourhood of magnets, they are traversed by electric currents, and it appears that the intensity of the currents varies directly as the conducting power of the moving body, if other things are equal. By employing therefore a constant magnetic arrangement, and causing different conductors to move similarly in the field of force, we would only have to measure the currents in order to obtain the specific conducting powers. This method has confirmed the results previously obtained by laborious and unsatisfactory experiment. Copper, gold, and silver are the best conductors, being as 688, 600, and 466. Lead is only as 52, mercury between 10 and 20. Pouillet has endeavoured to estimate the conducting powers of liquids, and to compare them with those of the metals. For the conducting power of the saturated solution of sulphate of copper, the most powerful liquid that he examined, he found a value only a twelve millionth part of that of gold. We obtain from this example a good idea of the width of range taken by bodies, in regard to conductivity: for the liquid here compared with gold, is an excellent conductor compared with other bodies usually consigned to the class of conductors.

Currents, Oceanic. See OCEAN and TIDES.

Curvature. Literally the amount or degree of the *bending* of any mathematical curve. The general principle of the treatment of all questions of curvature is easily explained. The direction of a straight line is determined when two points in the line are determined. Through any two contiguous or *elementary* points in any curve, a straight line, and only one straight line, can be drawn. That straight line is the *tangent*; or the straight line which of all others, most nearly coincides with the curve at the point or points through which it is drawn. The position and magnitude of a *circle* again is determined by the position of any *three* points in its circumference: through *three contiguous points* in any curve, therefore, a *circle* may be supposed to be described. And as the *tangent* indicates the direction, this circle—named the osculating or Equicurve Circle—indicates or measures the bending, or curvature of the curve at the said point. The finest mathematical theory of curvature yet given is that of Lagrange, and it rests on the foregoing view. The curvature of any Line is *technically, single, or double*. If the line is in one plane, its curvature is single; if on the other hand it is a twisting line in space, it is termed a curve of *double curvature*. The theory of all such curves is complete; although it cannot be said not to be cumbrous. See QUATERNION.

Cyanometer. An instrument invented by Saussure for measuring the intensity of the blue of the sky. Imagine a band of rectangles, of which the first is of the deepest cobalt blue, whilst the last is almost white; the intermediate rect-

angles presenting all imaginable shades between these extremes. By comparing this scale with the sky, it is easy to detect with which rectangle the shade of the sky corresponds; and the number attached to that rectangle will indicate the degree of blue. By an ingenious process, Saussure obtained *fifty-one* shades regularly graduated, between white and black: so that the scale of this Cyanometer comprises fifty-three degrees, corresponding to combinations of white and deep blue, in definite proportions. The instrument, simple as it is, fully answers its purposes.

Cycle. A name applied to an interval of time, after the passing of which certain phenomena, chiefly astronomical, recur in the same order and with the same circumstances as during its continuance. No phenomenon in the universe will in all likelihood ever again recur identically. All is in unceasing mutation—no star that has once been in any place in the infinite space will, for ever, return to it, or any cloud sky that has once shaded the earth will ever renew itself. But this does not prevent the succession of circumstances nearly similar, in cycles of nearly constant length. Thus though the length of the year changes by infinitesimal amounts, we can take a certain approximation to it, as quite near enough for all purposes, and we can be sure that after it passes, the sun will pass through a series of positions, which to us appear the same or practically so, as during the cycle of the year. It would be impossible in this article to name and give an account of all the astronomical cycles within which phenomena recur. The year and the month, as the most important of them, will be noticed elsewhere. The word *cycle* is applied in a somewhat narrower meaning than that which we have explained, and which properly belongs to it. The year and the month depend on the recurrence of one astronomical phenomena, which again does not depend on the recurrence of several others. There are special phenomena such as eclipses, whose recurrence is the result of peculiar conjunctions of phenomena, and the name cycle is properly applied where these phenomena are themselves recurring in the interval from their commencement, together, to their recommencement. We shall explain some of them here in order. And first—the methods by which the commencement of the year and the day are adjusted. By far the most important adjustment which we have in this regard are found detailed in the articles BISSEXTILE and CALENDAR. The first we shall specify here is what is called the *solar cycle*, or cycle of Sundays. This is chiefly of chronological interest. Were our year composed of an exact number of weeks, as 52 weeks, we should have a constant recurrence of days in the same order, and if Sunday were the first day of the year, it would be the first day of the year for ever after. But the year is made up of 52 weeks and a day. Hence

Sunday (take any other day of the week as well) goes backward a day every year. The first of this year is on a Sunday, suppose—then that of next year will be Monday, of next—Tuesday, and so on. In this way we should come back to Sunday after seven years, and go through the same series of changes. But the calculation is again disturbed. Suppose the first year to be e.g. 1854. Then next year (1855) will commence on a Monday, this beginning, suppose, on Sunday. Next year (1856) commences on Tuesday, but it contains 52 weeks and 2 days. Hence the next year will commence not on Wednesday, but on Thursday. This upsets therefore the cycle of seven years which we had imagined. We come back to a year commencing with Sunday—1860, but we do not go through the days, taking all but Wednesday as commencements of the year. The year 1860 has also two odd days, and the next, 1861, commences on Tuesday. We will go on. So then—Wednesday, Thursday, Friday—then (omitting the fourth day, Saturday) Sunday, with still a change in the order. Monday, Tuesday, Wednesday, omit Thursday, Friday, Saturday, Sunday, Monday, omit Tuesday, Wednesday, Thursday, Friday, Saturday, omit Sunday, Monday, Tuesday, Wednesday, Thursday, omit Friday, and so on. Each of these cycles of seven years would be complete but for this omission of every fourth day in the succession of commencing days. All these omissions go in the one direction—the pushing forward of the commencing day by one additional day. There is one of them every four years. In seven of these four-year periods there will be seven of them, and the year will therefore be seven days or one week pushed forward as to its commencing day. Here therefore at the end of this time we will get back to the same day of the week for the commencing day, with the same series of omissions to succeed it for another period of seven of those four-year periods. In 28 years therefore there will be a constant recurrence of the same series of days of commencement of the year. Thus for 1854, 1855, 1856, 1857, the days commencing are Sunday, Monday, Tuesday, Thursday, and so on for the succeeding years. The same series begins again at 1882, and will go on for 28 years exactly the same. This period of 28 years is called the *Solar Cycle*. For the old style, in which the Julian year alone was employed, the method was perfect. But according to the Gregorian correction—(see *DICTIONARY*)—the years 1700, 1800, 1900, are not leap years, though divisible by 4, nor any number of hundreds, which is not itself also divisible by 4. Hence at 1900 the cycle is interrupted. The year 1900 should have its commencing day two days behind that of next year. It has Monday. The year 1901 should have Wednesday, in order that the cycle might sit. But the year 1900 is not, though the

end of one of the periods of four, one which has two odd days, but only one. Hence Tuesday will be the commencing day of 1901, and so it goes on. But as Wednesday was the commencing day of 1883 (1901—28) the comparison between the 28 years just then passed and the next 28 would be all at fault, and would, if followed, put us a day too far forward in our reckoning until the next date of disturbance. The series of days will require then to be changed for 1901 and the succeeding years, and will go on so changed until the next interruption. Usually these interruptions will recur every 100th year, but 2000 is a leap year, and the cycle of days marked in 1900 will go on uninterrupted for 200 years in consequence, requiring new change at 2100, then requiring still another change at 2200, and so on. It will be useful to give for this century the days of commencement:—1800, Tuesday; 1801, Thursday; 1802, Friday; 1803, Saturday; 1804, Sunday; 1805, Tuesday; 1806, Wednesday; 1807, Thursday; 1808, Friday; 1809, Tuesday; 1810, Monday; 1811, Tuesday; 1812, Wednesday; 1813, Friday; 1814, Saturday; 1815, Sunday; 1816, Monday; 1817, Wednesday; 1818, Thursday; 1819, Friday; 1820, Saturday; 1821, Monday; 1822, Tuesday; 1823, Wednesday; 1824, Thursday; 1825, Saturday; 1826, Sunday; 1827, Monday.—If to each of these numbers we add 28, or 56, or 84, we will get the series of years for which the commencing day is the same, and also the commencement of a like cycle. Thus $1806 + 28 = 1834$, has Wednesday for its first day (as 1806 has). So also $1806 + 56 = 1862$, and so also $1806 + 84 = 1890$. When we add still higher multiples of 28, i.e. 112, 140, &c., we get $1806 + 112 = 1918$, and here we would be led a day too far forward. Tuesday therefore is the day for this, and so Tuesday is the commencing day of 1918 + any multiple of 28, as long as this does not reach 2100.—*Cycle of Indiction*. A period, (quite arbitrary,) of 15 years, originated by the issuing of a tribute edict by the Roman emperors every fifteen years. It is of frequent occurrence in old history, chiefly ecclesiastical. The position of any year in the cycle of indiction may be found by adding 8 and dividing by 15. Thus $1855 + 8 = 1863$, and therefore this is the 13th year of such a cycle. If we take 812 from the year given and divide by 15, thus $1855 - 812 = 1043$, $\frac{1043}{15} = 69 \frac{8}{15}$, the remainder 8 indicates the year of such a cycle as before, and the quotient 69 gives the number of the cycles past. We are therefore living in the 13th year of the 108d cycle of indiction. The year 818 is taken as the first year of the first cycle—the origin of this chronological period.—There is

a period or cycle—called variously the Sothiac period—the Canicular year—the Annus Magnus or Annus Vagus, which merely requires notice. It was used among the Egyptians. Their original practice was to have 12 months of 30 days each, intercalating 5 days, as a full equivalent for the year. They very soon found the length of the year to be $365\frac{1}{4}$ days. But the priests attached mystic importance to the dates of their recurring festivals, fixed according to the old method, and would not introduce the fourth day. Hence, while the people adopted a year measured by the recurrence of what is called the heliacal rising of Sirius, the priests instituted the Sothiac period of 365×4 years, within which it is evident that the error of $\frac{1}{4}$ of a day, constantly accumulating, would amount to a complete year of 365 days, which would then be considered as non-existent, so that, thus the 1461st year commenced with an agreement between the sacred and popular year. It is probable that the institution did not last over one complete cycle. Had it done so, it could not have failed to be noticed that 1460 years would not serve for such a period, because $\frac{1}{4}$ of a day is not the amount of annual error, but 1508 years rather.—The next periods of importance are connected with the adjustment of the moon's motion with that of the sun, and in consequence—as on their relative positions eclipses depend, also with the calculation and prediction of eclipses.—The first is the Metonic cycle of 235 lunations, introduced by Meton, who lived in Athens about 482 B.C. A lunation is the period from full moon to full moon, or from new moon to new moon. The period of 235 lunations of 29.53059 days each gives 6939.69 days. Now 19 years of $365\frac{1}{4}$ days each give 6939.75 days. Hence the recurrence of new moons, at the same parts of a cycle of 19 years, if the Julian method of reckoning the year were adopted, would be pretty accurate. Each cycle then would indeed be a falling back of .06 of a day in the occurrence of new moon, but this would not amount to a whole day until above 800 years. Hence, tabulating as in the solar cycle the dates of new and full moons for 19 years, we should have the same dates on which they would recur during each year removed from the former by any multiple of 19 years. Thus given the dates of all the new and full moons in 1854, we would have the same dates for 1873, 1892, &c. There would be slight disturbance, however, always to be allowed for, caused in this arrangement, by the fact that there is not a year of $365\frac{1}{4}$ days, but three years of 365 and four of 366. This might produce an error of nearly a day either way. Still the cycle was very useful. The Gregorian reformation of the calendar has yet further, however, deranged it, so much so indeed as to render new tables necessary, as in the solar cycle, for every time that the interruption comes.—The Metonic cycle of 235 lunations contains

also 255.021 nodical months, that is, months which are measured by the interval between the moon's orbital intersections of the ecliptic. At the recommencement of a Metonic cycle, therefore, the moon is very near the same position relative to her node, as she was at the beginning of it. In .021 of a nodical month she will be accurately at the same point. Now, eclipses, both of sun and moon, depend, as we shall see (ECLIPSES) upon the new and full moon, and on the position of the moon in her node. When the new moon is at her node there is a solar eclipse; when the full moon is so a lunar one. Hence in the successive Metonic cycles the eclipses will run at the interval of .021 of a nodical month from identical dates; that is, however, $.021 \times 27.212$ days, rather more than half a day. Hence the Metonic cycle will not serve very well as a cycle of eclipses, but will very well for marking the corrections pointed out to suit the Julian and Gregorian Calendars, as a cycle of lunations.—This cycle of 19 years, or 235 lunations, is used for finding Easter, being there called the cycle of the *Golden Number*. It is also called the *lunar cycle*. This latter term one readily understands; the former originates in the sanctity attributed to the church festivals, the dates of which the ancient church constantly fixed by periods of new moon. The methods of calculating Easter Day will be found in chronological treatises.—The next cycle which was constructed as an improvement upon the Metonic, was the *Calippic*, due to Calippus, a disciple of Plato, who flourished about 330 B.C. He found the errors of the Metonic cycle very manifest in observing an eclipse near the time of the death of Alexander the Great. He merely made a cycle of four times as much length as that of Meton, all but 1 day. His cycle contained 76 years all but 1 day therefore, and it contained still more near approximation than Meton's to an exact coincidence of lunations and nodes. There were in it very nearly 940 lunations, 1020 nodical months, and 1016 sidereal months. It had the faults of the Metonic cycle, less exaggerated than his. He commenced calculating his cycle from the new moon immediately following the summer solstice of 880 B.C. Meton's cycle commenced on the 15th July of the year 482.—The best period for the calculation of eclipses which has come to be very well known is the "Saros," a period of Chaldean origin. This period consists of 223 lunations. In that period there are 241.029 sidereal months, so that the moon at the end of it is very nearly in the same position in the sky as she was at the commencement. There are also 238.992 anomalistic months, so that she is very nearly in the same position in her own orbit also. There are besides 241.999 nodical months, so that she is very nearly in the same position regarding the ecliptic, having gone forward by .001 of a nodical month,

CYC

about 0.27 of a day. Now the occurrence of eclipses depends upon the position of the moon near her nodes, and her conjunction with or opposition to the sun. Here then, supposing her to be in opposition or conjunction, and at her node, at the commencement of a saros, she will be in conjunction or opposition again and very near her node (having passed it about 40 minutes before), at the end of the saros. Hence in this period all eclipses will very nearly recur. Chronologically, however, this is not equal to the Metonic or Calippic periods as not giving the dates of eclipses at once; but it is far more accurate, as giving the time of their occurrence. The 223 lunations make up 6585.32128 days or 18 years of 365 days each, 15 days, 7 hours, 40 minutes, 38 seconds. It has no definite period of commencement, so that if we choose to commence it in one year we may have five, or in another four leap years in the 18. In the first case the saros consists of 18 years, 10 days, 7 hours, 40 minutes, 38 seconds, and in the second the same with 1 day added to it. The original Chaldean period is 6585½ days, which is wonderfully accurate, being only in error by 19 minutes 22 seconds, and they were wont to treble the period in order to get at the exact number of days. This method secured nearly the ending of each saros in the same part of the day as the beginning of it, a point of great importance, as far as its use in predicting solar eclipses goes. Like all such periods, which make one recurring phenomenon coincide with another, the saros does not completely answer its end. The little differences of nearly 40 minutes in each Saros accumulates, and carries the moon out of the position where eclipses may occur—putting partial eclipses for total, and ultimately destroying the partial ones. The saros cannot well be used, therefore, as a means of discovering eclipses far removed from our times. In the saros there are generally about 70 eclipses, of which 29 are lunar, and 41 are solar, visible in some part of the earth. In the course of a year the number of eclipses so visible may be as many as seven and as few as two. See Article ECLIPSES.—The *Paschal Cycle* is an ecclesiastical one, exactly like the solar in principle. There the even disturbance of one day per week is not permitted by the introduction of leap year. Here the regular recurrence of Easter, on the same day of the year after 19 years, cannot take place on the same day of the week, because the commencement of the year does not. The two cycles of 19 and 28 years do not coincide, just as the two cycles of 7 and 4 years. The same principle which procured their coincidence in a larger cycle, by multiplying them together, does so here also. Hence 19×28 , or 532 is the period within which the recurrence of Easter on the same day of the year—for all the successive Easter days of that period takes place.—The

CYL

Julian Cycle is a contrivance on the very same principle, introduced by Joseph Scaliger, to make the cycle of indiction and the solar and lunar cycles, coincide. It is merely $28 \times 19 \times 15$ years, or 7980 years. Its commencement was fixed at 4713 B.C. Hence by subtracting the number of any year B.C. from 4714, or adding that of any year yet reached A.D. to 4713, we will get the year of the Julian period. By dividing this by 28 we get the year of a standard solar cycle, in the remainder by 15 that of indiction, and by 19 that of a standard lunar cycle.

Cycloid. A curve thus described. Take a circle and mark on it one point. Roll this circle along a straight line in any plane, and observe the various points successively covered by the marked one on the circle. The curve so traced will be a *cycloid*. Galileo was the first to remark it in 1615. Its equations are $x = a(\omega - \sin \omega)$ and $y = a \text{ versin } \omega$, where a is the radius and ω the angle between the radius to the point, (x, y) and the radius to the point where the generating circle touches the constant straight line. They may also be put in these two other forms:—

$$\frac{y}{a} = \text{versin } \frac{x + \sqrt{(2ay - y^2)}}{a}$$

$$\frac{dy}{dx} = \cot \frac{1}{2} \omega$$

Cylinder. A solid terminated by three surfaces, one of which is convex and continuous—being in the cylinder proper, circular—the other two parallel. A *right cylinder* is one in which the line joining the centres of the limiting circles is perpendicular to their plane. Every other cylinder is oblique. A right cylinder, in the confined sense we have indicated, may be conceived as described by a rectangle revolving round one of its sides as in the figure, and an oblique one may be formed by cutting a right cylinder slant across. The more philosophical definition of a cylinder as including all possible ones, would be that an infinite number of infinitely thin planes, bounded by curves of the same size and character, returning into themselves, are laid one above the other, the cylinder being the complete outline of the solid so formed. The line between the centres is the axis of the cylinder, and the two parallel sides are the bases. The height is the perpendicular distance between the bases. The content of the cylinder is the product of the height by the area of either base. The convex surface is equal to the product of the circumference of the base by the length. Similar cylinders are those with similar bases, having their axes inclined similarly, and their proportion to the linear dimensions of the bases the same. The oblique cylinder with elliptic ends is sometimes called a *cylindroid*.

D

DAG

Daguerreotype. The beautiful department of photographic art which is so designated, derives its name from its inventor, Daguerre, who, along with another indefatigable French experimentalist, Niepce, after long continued researches, succeeded in perfecting its different processes, and published them to the world in July, 1839. A short *rationale* of the art will first be given, and afterwards a description of the different steps necessary for the production of a Daguerrean picture. A surface of pure silver is caused to combine with iodine, and in the more recently improved methods also with bromine, whereby a film of ioduret and bromuret of silver is produced which is exquisitely sensitive to light, in such a way that if exposed even for a single second to a feeble daylight an incipient change is produced in it, which though not obvious by mere inspection, yet becomes evident by the facility which it has acquired of condensing vapours, particularly that of metallic mercury, on its surface. If the plate be long exposed to light, a change on the surface becomes apparent without any development by mercurial vapours, though this requires a much longer time, at least 1000 times greater than that which is necessary to determine the first affinity for mercury. If, instead of the plate having been exposed to diffused light, it be put in the field of the camera obscura, the image impresses the magical change on the different parts of the surface, to an extent proportionate to the intensity of the light (to speak simply), and thus a latent image of the picture is produced, which is afterwards brought out by exposure to mercurial vapour, which, by adhering to the parts acted on by the light, gives them a white appearance, while the parts on which the light has not acted remain of the original dark aspect of the polished silver. The sensitive bromo-ioduret of silver is now removed from the plate by a weak solution of hyposulphite of soda in water, after which it is washed, and is no longer sensitive to light. It is then protected and strengthened in its appearance by boiling on its surface a solution of chloride of gold. Afterwards it is carefully covered by glass, and protected from the contact of air and damp. Even with all precautions, it is to be regretted that, owing to the extremely oxidizable nature of mercury and silver, the brilliant aspect of these beautiful phantoms after a time begins to fade; and, except in the case of their being hermetically sealed in cases of glass, there is reason to believe that in comparatively few years most of them will perish.—As to the practical operations of the Daguerreotypist, space compels us to be brief. The silverized tablets of copper are to be had of the shops. They must be again polished immediately before being exposed to the iodine. Olive oil and finely pow-

DAG

dered pumice are first rubbed on by circular strokes of a dossil of fine cotton wool. The wool is again and again renewed, till the whole of the oil and pumice are removed, after which the surface is wetted by a piece of cotton dipped in one part of nitric acid to fourteen of water, which is afterwards wiped off by clean cotton, and fine pumice reapplied. It may then be finished by circular movements or strokes, as they are called, on a piece of velvet, till a fine black polish comes over the whole surface. It is now placed in the iodine box, of which a representation is annexed, into which a small quantity of iodine has been

Fig. 1.

put, and is allowed to remain till the surface is of a pale yellow colour when examined in a feeble light. It may now be placed in the camera, but it can previously be rendered much more sensitive by exposure to the vapour of bromine, rising from a small quantity of bromide of lime placed in a box similar to the iodine box, till it is of a rose colour; after which it is to be exposed in the camera for a period varying from a fraction of a second to a few minutes, the time depending only on the sensitiveness of the surface and the strength of the light. This, experience only can teach. The image is now to be developed, by placing the plate in the mercurial box, at a height of a few inches from a small metallic pan of mercury, in which is placed a thermometer, the plate being inclined at an angle of 45° to the rising vapour. A spirit lamp is placed under the pan, and the temperature raised so as not to exceed 167° Fahr. The development of the image is to be watched by the light of a candle held near the small window in the side of the mercurial box, while the eye is placed at the other. The plate is then to be removed from the box, and while still in the dark room it is to be placed for a moment under water, and then

DAG

moved to and fro in a solution of hyposulphite of soda, till the yellow colour is removed, and then washed in a gentle stream of water, the water

Fig. 2.

being afterwards blown from the surface if any drops adhere, lest in drying they should leave marks. The plate is now to be held by a small pair of pliers, and covered by a solution of gold, made by dissolving four grains of chloride gold in eight ounces of water, and sixteen grains of hyposulphite of soda in two ounces of water. Mix the two solutions, gradually shaking them together. This liquid keeps well, and, as above directed, is poured in sufficient quantity to cover the plate, which is then held over a spirit lamp till boiling is produced, and a considerable portion is evaporated, after which the remainder is to be thrown off, and the plate quickly washed and dried.—It cannot be denied that though the Daguerreotype, as far as sharpness and delicacy of detail is concerned, is the most perfect of all the photographic processes, yet it is the most difficult of manipulation. So much is this the case, and so difficult is it to get the plates sufficiently clear and free from scratches, that it is scarcely a process for an amateur. The metallic glare of the pictures and the livid look which they frequently assume are also objections from which the results of the arts described under the heads CALOTYPE and COLLONON are free, and, as already hinted at, there is reason to believe that the pictures so produced are less liable to decay. They can also be more easily obtained of a larger size, and can be manipulated in the fields for the

DAL

production of out-door views far more easily than the plates of the Daguerreotype process. It ought perhaps to be stated, as an important point in manipulation, and also as curious in itself, that a momentary exposure of a plate to bromine vapour which has, after being made sensitive, been exposed in the camera, completely effaces the impression, so that no image would be developed were it submitted to mercurial vapour; and that the same action of the bromine renders the surface again sensitive. So that it is unnecessary to clean the plate, if before developing we suspect the picture to be imperfect. All that is necessary is to submit it for a little to bromine, and slip it into the slide of the camera again to be exposed.—It is also worthy of notice that it is in connection with the Daguerreotype process that the most successful attempts have been made to procure, directly by photography, pictures in their natural colours, an achievement which, could it be accomplished, would leave little to be desired in this beautiful art, which has already done so much for the instruction and delight of mankind and for the glory of its illustrious discoverer.

Daltonism. A name given to that imperfect sensation or appreciation of colours with which many persons are afflicted: it is derived from the name of the great chemist Dalton, who had the infirmity in excess. The imperfection is a singular one: the form of objects is readily discerned and judged of; nay, the eye is sensible to the smallest amount of light: but the sensitive or perceptive apparatus is apathetic to certain tints; and either the former does not transmit notice of them to the brain, or the latter cannot judge of the transmitted intimation. Seebeck closely investigated the infirmity. He divided Daltonians into two classes,—the *first* composed of persons who are deceived rather with regard to shades of colour, than as to different colours; who confound, for instance, clear orange with pure yellow, lilac with bluish-gray, &c., &c.: the *second*, of those who really do not know many distinct colours, having for the most part an extremely feeble appreciation of the less refrangible rays of the spectrum, or of the rays near the red end. Two general conclusions are drawn by Seebeck from a large series of observations. 1. Daltonism never affects the yellow rays: every eye, however imperfect otherwise, distinguishes yellow. 2. The sensations of complementary colours, are inseparable; so that the eye is sensible or insensible to both at once: for instance the eye that perceives *blue*, will also perceive *orange*; the eye that cannot distinguish *red* will not be able to distinguish *green*, &c., &c. There is a far greater number of *Daltonians* than is generally supposed; more among males than among females: the defect is also hereditary. Dr. George Wilson of Edinburgh not unwisely asks whether it may not often blind railway guards to the character of those coloured

DAL

signals which it so much behoves that they interpret aright? By a very simple means Daltonians may be made aware of their error, viz., by the use of coloured glasses. If, for instance, one's eye confounds green with red, it is enough to use a red glass, and the difference of the colours will, to his great astonishment, be perceived in an instant. See memoirs by Seebeck, Wartmann, Szokalski, and Dr. George Wilson.

Dalton's Law:—that two gases placed beside each other in a given space, expand towards each other, ultimately, as toward vacuum. Thus, for example, if carbonic acid and common air be put into one vessel, the carbonic acid will spread after a time through the whole vessel as though air were not present at all; and the air will, in its turn, expand as if there were no carbonic acid. The pressure upon any part of the vessel will be the sum of the pressures of the expanded portions. Thus, if *a* of the vessel be filled at first with the acid, and *b* with the air, the volume of each will become $a + b$, and according to Marriotte's law,

the pressure of the first will be $\frac{a}{a+b}$ of what it was, and of the second $\frac{b}{a+b}$ of what it was.

Suppose *p* and *p'* the two pressures on each square inch, then the ultimate pressure will be $\frac{ap + bp'}{a+b}$. If the two gases have originally

the same pressure *p*, $\frac{ap + bp'}{a+b}$ will become equal to *p*. That is, the pressure on the sides of a vessel, acted on by a given internal pressure, is not altered by the mixture within it of two gases, originally of the same elasticity.—Dalton's law does not require that the mixture of gases, and the completion of the process, should be instantaneous. In fact, it never is. If, for example, carbonic acid at atmospheric pressure be enclosed in a vessel with a plaster of Paris lid, put over water, and a small hole be bored in the lid, the water will rise until it nearly fills the vessel. If the operation of Dalton's law were instantaneous, there could be no such rising, the carbonic acid would immediately disappear almost entirely into the air, and the air would take its place; but the pressure would be constant, and equal to that of the atmosphere upon the outside water. In point of fact, some hours would elapse before the level had sunk to its original height. Most gases, indeed, expanding towards vacuum, do so with violent accompanying explosions. Gases mixing according to this law, conduct themselves with perfect quietude.

Dasymeter. An instrument invented in 1780 by M. Fouchy, with the view of ascertaining the density of different descriptions of gas. It is merely a globe of very thin glass, capable therefore of nearly floating in air, and which is weighed against ordinary weights in dif-

DAY

ferent gases. The principle of Archimedes (BALANCE—HYDROSTATIC) will immediately show the reader how the instrument should be used. The glass ball displaces its own volume of the gas; and the weight of that amount is deducible from comparison between the ball weighed in a gas, and *in vacuo* or an atmosphere of known density. We thus come to know the density of the gas.

Dawn. During a considerable time before the morning Sun is visible, there is not complete darkness in the sky. The luminary appears at the very moment when his *direct* rays reach the eye; and this partial illumination must be due to some other influence; principally to the reflective power of the atmosphere. The sunlight enters the atmosphere before it reaches us directly. The

spectator at *E* will not see the sun until he rises above the horizontal line *MN*, but when he is at *s* his lowest ray will be along *sPK*. As the other rays will all pass on the upper side of *sK*, unintercepted by the earth, if we conceive the ring *LFG* to be the outer limit of the atmosphere, the whole atmospherical space, except that portion from *KP* round to the similar line on the other side, will be filled with light. Hence light will freely pass through the atmosphere *FOK*, which is within the range of vision of the spectator at *E*. If this atmosphere allowed light to pass freely through it, these rays would not reach us: but it possesses the property of a mirror, reflecting part of these rays back; and so it gives us partial light. This light is called the dawn. It has commenced whenever the lowest ray has passed into the space *FD*; and terminates as soon as the sun has risen to the line *FD* or its production.

Day. Applied, in ordinary language, to the period of light from its appearance to its disappearance. This period (see DAWN and TWILIGHT) is somewhat indefinite, and its length varies in different seasons of the year. In this sense the word could never become a scientific term. The scientific day includes the night-time, and consists of 24 hours. The old name, which was synonymous with it, is *nycthemeron*. According to this use, we have what is called the *true solar day*, the *mean solar day*, and the *sidereal day*. The true solar day is the interval which elapses, between two successive transits of the sun over the same meridian. But this interval is not uniform throughout the year. Supposing a watch adjusted to keep time with the sun, it would require to be moved forward or backward almost every week. A correct watch goes regularly,—but the sun is irregular in his move-

DAY

ment. Hence the idea of a *mean solar day*. This is precisely what its name imports. The whole of the days for a year are added together; and the interval between the first and the last of them divided by their number. The result is the *mean solar day*. The correction by which the true solar time is brought to mean solar time is the *Equation of time*. See EQUATION.—This correction is sufficient for most physical purposes. The astronomical or *sidereal day* is obtained otherwise. This sidereal day is measured by the rotation of the earth. Our globe moves round an axis; and so makes all objects without and beyond it, to change their apparent positions, and gradually to return to them. But this rotation of the earth is always accomplished in exactly the same time; or if it vary at all, it has been proved by Laplace, to vary so little as to be altogether insensible during the whole duration of our present era. The period of this diurnal motion may be taken, therefore, as an absolute and invariable measure of time; and that period, or the *sidereal day*, is the interval between two successive transits or culminations of a *fixed star*. Now, as the apparent motion of the sun is backward among the stars, the sidereal day must be shorter than the mean solar day; and if the sidereal and solar day should begin together, the one would gain, in one year, one whole day upon the other.—Taking the mean solar day as the standard, the length of the sidereal day is 23 hours, 56 minutes, 4.092 seconds. This period is divided into 24, giving sidereal hours; then, subdivided into 60, and that again into 60, giving sidereal minutes and seconds. They will all be shorter than the mean solar hours, minutes, and seconds, in the proportion of 24 hours to 23h 56' 4.092" (as 86,400 to 86,164.092). Pendulums are readily constructed of such a length as to beat sidereal, instead of mean solar seconds; and those of astronomical clocks are so constructed.—The mean solar day is equivalent, to what is ordinarily called the civil day. The four times of the day's commencement which have been in use at different times are—mid-day (period of transit), midnight (time of equal division of the interval of transit), sunrise, and sunset. The Babylonians used to commence their day at sunrise, and reckoned round again 24 hours to the next sunrise.—The Egyptians began their day at midnight: Hippocrates introduced, and Copernicus confirmed the use of this in astronomy. It is difficult, however, to see what this practice, still followed, has to recommend it. There is no physical event coincident with the commencement so made, and in the case of the astronomer especially, the observations he makes, being many of them, in the night, would be so recorded as occurring on different days. This gives rise to a considerable amount of trouble. In observatories, the day is calculated as 24 hours, and not as two periods of 12 hours each.

DEC

Thus, the hour before its commencement is the 23d of the preceding day.—The method of commencing the day at noon is, of course, that of ordinary life.

Decimal Coinage.—Until within the last sixty or eighty years, decimal coinage was little known. Almost all the European states employed systems of coins bearing more or less analogy to our own. The steps from one coin of account to the next, like the majority of those used in the progression of weights and measures, were made by numbers apparently chosen for their great divisibility, more especially by binary factors. The favourite numbers were 20, 12, 16, 8, and 4; there was one example of the use of the inconvenient number 7, and another in which the factor 3 was employed. Thus England has had from time immemorial her present money table of account. In France the old money scale was 12 deniers = 1 sou, 20 sous = 1 livre, which, except that the livre was very soon depreciated to an extremely low value, was the precise counterpart of our pounds, shillings, and pence. Piedmont, Sardinia, Liguria, Lombardy, and Tuscany, had the same system, the names of the coins were changed to lira, sol, and denier; and in the case of Tuscany, a coin of 7 lire, called a *scudi*, was added at the top of the scale. In Belgium, several systems of account existed, bearing a more or less close analogy to the English and French scales. There was the Brabant florin of 20 sous, each sou being 12 deniers, and the livre tournois, which was divided in the same way. Another scale in use in Belgium was 16 deniers = 1 sou, 20 sous = 1 florin. A fourth was 8 mittes = 1 denier, 8 deniers = 1 groa, 12 gros = 1 schilling, 20 schillings = 1 livre de gros. In the Netherlands, 16 pennings made 1 stiver, and 20 stivers 1 guilder. In the systems of some other countries, the prevalence of the same factors was observable in a greater or less degree. In Russia, on the other hand, the decimal, or rather centesimal, scale of 100 copecks = 1 rouble, has long existed; and in Portugal, accounts were kept by simply stating in common arithmetical notation the numbers of an imaginary minute coin, called a *rei*, contained in the sum to be recorded, the term *milrei* being used, as its etymology imports, to denote 1,000 reis. In the actual Portuguese coins, the law of the English and French coinages is traceable in a modified shape. The modern movement in favour of decimal coins was commenced by the United States of America immediately after the declaration of independence. Their previous system of account had been identical with that of England, except that the value of the pound had been more or less depreciated in almost all the provinces. The coins in circulation were principally Spanish dollars, and the dollar was on that account selected as the unit of the new coinage. It was divided into 10 dimes, the dime into 10

cents, and the cent into 10 mills; but though all these coins have been put into circulation, dollars and cents alone have survived as instruments of reckoning, dimes having never been used in accounts, and half-cents, quarter-cents, &c., having superseded mills in the reckoning below the cent. The French Revolution gave the next impulse to decimalization. A very symmetrical system, embracing decimal coins, weights and measures, and a decimal reckoning of time, starting from the establishment of the Republic as its epoch, was attempted to be introduced, with the double view of attaining to scientific uniformity and obliterating the landmarks of the past. The coinage as well as the metrical system has proved permanent. The transition was very simple. The franc is identical with the average value of the old livre, which varied somewhat in different provinces. This was divided into ten décimes, each of which was therefore equal to two of the old sous, and the décime was again divided into ten centimes, or hundredth parts of the franc. As happened in the case of the dime of the United States, the décime has been found useless, and accounts are kept simply in francs and centimes. The example of France was followed (in most instances by compulsion, but in some voluntarily) by many surrounding countries, and the franc and centime coinage, or some equivalent system, is now established by law in Belgium, Switzerland, the Netherlands, and a great part of Italy. The influence of the United States has, in like manner, so far modified the quasi-English system of Canada, that the provincial legislature has legalized the dollar and cent reckoning as a method of account.—The extent to which the legal establishment of decimal coins has succeeded in different countries in extirpating the old methods of account was very fully investigated by the Decimal Coinage Commission of 1856. (See Prelim. Report and App., 1857, and Final Report and App., 1859.) The results appear to be, that in the United States, France, and some other countries, the new systems have become firmly established in commercial transactions. Belgium having been compelled to adopt the French notation in 1808, repudiated it after the Peace of Paris, and re-adopted it in 1832; but the change has not yet become radical and complete, and people are said still to be obliged to use tables of the various monies, past and present. Comparatively little impression seems to have been made in any country upon the habits of retail traders. In France, where the experiment has been most successful, shopkeepers speak of sous in preference to centimes. In America, retail prices are more frequently fixed with reference to the old provincial shilling and pence coinages, which have ceased to exist for upwards of sixty years, than in terms of dollars and cents. The same tenacity of habit has been shown by the shopkeepers and poorer classes in other countries, long after deci-

mal accounts have become universal in large transactions.—The project of introducing decimal subdivision into the coinage and general metrical system of this country has been much canvassed from 1815 to the present time (1859). The first official step in this direction was the appointment, in 1816, of a Commission to consider the advisability of establishing a more uniform system of weights and measures. The Commissioners (Sir J. Banks, Sir G. Clerk, Mr. Gilbert, Dr. Wollaston, Dr. Young, and Capt. Kater) reported that a duodecimal scale was far preferable to a decimal one, on account of the facility which it afforded for expressing such quantities as a-third, a-fourth, and a-sixth of a foot, and the like, and for continual halving of measures of quantity and weight. In 1824, a proposal by Sir John Wrottesley to introduce a decimal coinage by reducing the farthing from $\frac{1}{4}$ to $\frac{1}{1000}$ of a pound, and by coining double shillings, was not very favourably received, but the scheme (now known as the pound and mil scheme) has since acquired considerable importance. In 1838, a Commission (comprising Mr. Airy, the Astronomer-Royal, Mr. Bailey, Mr. Drinkwater Bethune, Sir J. Herschel, Sir J. Shaw Lefevre, Sir J. Lubbock, Dr. Peacock, and Mr. Sheepshanks) was appointed to consider the best method of restoring the standards of weight and measure which had been destroyed in the fire at the Houses of Parliament. Their report, in 1841, gave a new impetus to the decimal movement. Their attention was drawn to the subject by the consideration of the best method of subdividing the units of weight and measure, and they recorded a very decided opinion in favour of the establishment of the pound and mil coinage as a preparatory step to a general decimal metrical scale.—A supplementary Commission on the restoration of the standards, composed of many of the old members, with the addition of the Marquis of Northampton, Lord Rosse, Lord Wrottesley, and Professor Miller, reiterated the recommendations of their predecessors. In 1847, the first positive step towards decimals was taken in the House of Commons, by the adoption of Sir John Bowring's proposal to coin a two-shilling piece, which was subsequently acted on by the issue of the florin now in circulation. This was followed by the appointment of a Committee of the House of Commons to consider the practicability and advantage of adopting a decimal system of coinage. The Committee reported, in 1853, decidedly in favour of the pound and mil scheme, but the discussion which followed brought out a number of rival decimal schemes, and exhibited some advantages of the existing system, which had not been brought before the attention of the Committee. In 1855, however, a resolution of the House of Commons was passed in favour of the further extension of the decimal system; but before taking any final step, the Government

referred the question to a Commission, composed of Lord Montagu, Lord Overstone, and Mr. Hubbard. Much additional information was collected by the Commission, and one point which had been previously neglected, was made the subject of especial investigation, viz., the comparative value of decimals and pounds, shillings, and pence, for the purposes of ordinary retail traffic. The results arrived at may be thus summed up:—

I. *As to account keeping and paper calculation.* That for these purposes a decimal is superior to any non-decimal coinage, inasmuch as it transmutates all money calculations from compound into simple arithmetic. But it appeared that in some insurance offices a system of decimal calculation was employed in conjunction with the present coinage; and those who had tried this method stated, that without any appreciable difficulty, they obtained all the advantages of decimal calculation, and that decimal coins would afford them no assistance at all. II. *As to retail traffic and mental calculation.* On this point it was established, that decimals are of much less service in mental than in written calculations, and that the divisibility of 12 and 20 by 2, 3, 4, and 6, and 2, 4, 5, and 10, respectively, greatly facilitates the common operations of mental arithmetic. Having regard to the scanty divisors of the number 10, the Commissioners came to the conclusion, that for common shop reckonings, most of which were worked in the head, the present coinage was more manageable than the pound and mil system would be. III. *As to the convenience of the coins of the two systems,* the advantage was ascertained to be on the side of pounds, shillings, and pence. The pound and mil notation offered no commercial minimum comparable with the penny, and the want of sufficient binary factors in the radix rendered the adjustment of the intermediate coins impossible without introducing inconvenient ratios. IV. *As to the difficulties of transition.* The experience of foreign countries proved the extreme difficulty of uprooting old habits. The mil (or new farthing) of the proposed decimal scale being $\frac{1}{4}$ of a shilling, and our farthing $\frac{1}{4}$, it followed that no number of pence, except multiples of sixpence, could be exactly translated into equivalents in the pound and mil system. Thus a penny toll would be represented by $4\frac{1}{2}$ mils, and could not be paid in the new coin. These and other difficulties of an analogous kind, arising from the incommensurability of the two systems of coins, were considered to render the transition (even if otherwise desirable) an extremely hazardous experiment. Other decimal schemes were found to be free from some of these inconveniences, but they were all rejected as impracticable on account of the aversion of men of business to be deprived of the pound as a principal coin of account. The report accordingly pronounces against any attempt to introduce the decimal principle into the coinage,

and may be regarded as having finally established the intrinsic superiority of the English coinage to any decimal or non-decimal system which has ever been founded or proposed.

Declination (of a Star). The angular distance between any star and the pole, is called the polar distance of the star. The complement of this is the declination, as we term it;—it requires, however, to be corrected, so that it may become the same as we should have, if looking from the centre of the earth. It is almost the same, and the difference is too small to be sensible in the case of the stars. It is not so with the sun and planets. The declination may be defined, also, as that part of a great circle passing through the star, which is intercepted between the star and the celestial equator. Declination and right ascension are the usual data for fixing the place of a star. Circles of declination correspond to what are meridian lines upon the terrestrial globe—circles, namely, described through the pole and the given star. Parallels of declination correspond to parallels of latitude, being smaller circles, parallel to the equator, all the points in which have the same declination.

Declination (of the Magnet) is the angle which the vertical plane through the magnetic axis of a magnetized bar, makes with the plane of the meridian of a place. See MAGNETISM.

Decomposition of Forces. See COMPOSITION.

Decomposition of Matter, is a term employed sometimes to denote the mere mechanical separation of particles; as in a rock which crumbles gradually under the constant action of mechanical forces. Generally, however, the phrase is employed in a different and indeed opposite sense, to signify the resolution of a chemical compound, into its several simple elements. The difference between this and the former kind lies in this, that here the decomposed particles possess properties entirely different from the smallest masses of the original whole; whereas in the former case the decomposed particles are identical in nature with the undecomposed mass.

Decussation. Arrangement of bodies in the form of an X. In optics the focus of a lens, i.e., the point through which the rays collected by the lens all pass is called the *point of decussation*. The phrase is little used.

Deferent. An ancient astronomical term. It means the circle, on which the centre of another moves; while a body is supposed to be passing along this latter itself. A planet moving round the sun as its centre, which centre again has a similar motion in space, may be taken as an example. The sun would here be moving in the deferent. The term belongs to the Ptolemaic hypothesis, and originated in it.

Deflection. A term employed to signify any bending of a body from the position which it would naturally be expected to

occupy. Thus, we talk of the planets being deflected in their orbits, when, instead of obeying the tangential force, they move in elliptic curves. It is used also in regard to the alteration of the true course of ships produced by currents or winds acting upon them. It is further used to signify that bending, or altering of direction, to which the rays of light are subject, which is now called DIFFRACTION (*q.v.*)

Degree: as an angular measure, is the 90th part of a right angle. As a circular measure, it is the arc comprised between two radii which make such an angle between them. Thus, a whole circle is divided into 360 degrees. Undoubtedly the origin of the division is to be found in the approximation to 360 days in which the sun performs his annual circuit;—one degree of the ecliptic being thus, very nearly, the amount of the sun's diurnal motion among the stars. The number 360, thus adopted, is convenient enough, as giving a very large number of sub-multiples, perhaps larger indeed than any similar number. Thus, of the first twelve natural numbers, only 7 and 11 are not sub-multiples of it.—Yet it is one of those cases where the decimal system might be introduced with very great advantage. Wallis, Briggs, Newton, and a great many of the continental philosophers, have suggested and enforced this. The French have actually adopted it. The facility with which decimal subdivisions can be expressed according to our notation is so great, that it is not to be exchanged for almost any other advantage.—The method adopted in France is this—the right angle is divided into 100, and therefore the circle into 400 equal parts. We divide our degrees, next, into 60ths, which we call “minutes,” and those again into 60ths, which we call “seconds.” They divide their degrees into 100ths, which are minutes, and these into 100ths again, which are seconds.—In reducing, therefore, angles measured in France to English, we must multiply the number of degrees by 9, and divide by 10, $\left(\frac{90}{100}\right)$

or simply subtract one tenth of the number.—We will multiply the number of minutes by 6, and divide by 10, $\left(\frac{60}{100}\right)$ to get the proper fraction of a degree, which would be the value of the specified quantity, if the degrees were the same, and then multiply by 9, dividing by 10, to arrive at the fraction of an English degree, similarly with the seconds.—We require to remember, then, that the English degree is $\frac{10}{9}$ ths of the French or centesimal degree—the

English minute $\frac{100}{54}$ ths, and the English second $\frac{1000}{324}$ of the French minute and second respectively.

Degree of Latitude, is the space, along the meridian, through which an observer must pass in order to alter his latitude by one degree. That is (see LATITUDE), the space along the meridian through which he must pass, in order that he may see the same star, one degree nearer to or farther from, the zenith.—This must be found by actual measurement. Eratosthenes is the earliest of whose measurement we find account. Taking a degree near Alexandria, 250 B.C., he found $694\frac{1}{2}$ stadia as the probable length (421,350 English feet, or $79\frac{1}{2}$ English miles). Ptolemy found it $59\frac{1}{2}$ English miles. Posidonius, in the time of Pompeius Magnus, found 68.95 as the length of the degree. This latter observation is remarkably accurate for the time; but the state of observation was such then, that we can scarce regard it as more than a fortunate guess. It was a matter, however, of great interest scientifically to know the length of the degree, and after the French came to make it their unit of measure, as in their metre ($\frac{1}{10,000,000}$ th of the quarter circumference of the earth) it became of great commercial value to know it exactly. Observations were accordingly instituted in great numbers.—Those which are recorded after the commencement of last century may be relied upon as generally correct. Huyghens, observing considerable discrepancies in the length of degrees obtained at different places, suggested the idea that this, and the alteration of length of the duration of a pendulum, might be explained by supposing the earth similar to Jupiter, which had just been discovered to be not quite spherical. The amount of ellipticity was calculated by Newton, and others; and is considered to be about $\frac{1}{800}$ th of the equatorial diameter.—It will be noticed, from any table of observations, that the degrees become generally longer towards the pole, and shorter at the equator. This arises from the bulging out of the earth at the equator, and its flattening at the pole. These two results at first appear contradictory. Cassini was misled in his first measurements by this. He found that his degrees diminished towards the poles (in all likelihood from errors of observation), and he considered this result in accordance with Newton's theory of the flattening of the earth at that place. His mistake being pointed out to him, he maintained that his experiments were nevertheless accurate; and that, in spite of gravity, the earth must be flat at the equator, and elongated instead of flattened at the poles. His persistence in the opinion was the occasion of two expeditions being despatched to Lapland and to the Equator; which established the general result of the increase of length in the degree, toward the poles.—If we consider in what manner the number of degrees of latitude over which one advances in a given space, is measured, we shall avoid Cassini's mistake. It is by the

DEG

angle between the vertical lines at the two places,—for it is to these that we refer the star which we observe. If we notice, for example, that a star that was in latitude 45° has changed to $47^{\circ} 10'$, we are certain that we have passed over $2^{\circ} 10'$ of latitude; and as both measurements refer to the respective vertical lines, we in fact measure their divergence. If now we take an egg, and draw perpendiculars at its end, and at its middle to the surface—two perpendiculars separate by half an inch at each spot will meet sooner at the end than at the middle, because the curve of the surface is greater there. Hence the angle contained between these two intersecting perpendiculars will be greater there; and as the space corresponding to it at the surface is the same in the two cases, the space corresponding to equal angles between the intersecting lines will be less at the end—that is, at the elongated part. Now this part corresponds to the equatorial, and the middle of the egg to the polar regions; and the lines of the perpendiculars are the lines of verticals at the spots; wherefore the length of a degree will be less at the equator than at the poles,—increasing from the equator to the poles, through the intermediate space.—The inequality of the lengths of a degree is thus, at once a proof and a consequence of the elliptical figure of the earth.

Degree of Longitude. is the space between two meridians that make an angle of 1° at the poles, measured by the arc of a circle,

Deg. Lat.	English Miles.	Deg. Lat.	English Miles.	Deg. Lat.	English Miles.

29	67-06	60	0-50	90	0-00

parallel to the equator, passing between them. It is always proportional to the cosine of the angle of latitude. The foregoing table of the

DER

lengths of a degree of longitude, is calculated according to this rule. It supposes the earth to have a diameter the same as at the Equator; where the length of a degree of latitude is assumed to be $69\frac{1}{8}$ English miles,—and also that the earth is perfectly spherical.

Deliquescence. A body is said to be deliquescent when it absorbs aqueous vapour from the air, and dissolves in it. All salts soluble in water are so far deliquescent. The property is made use of by chemists to dry gases which contain aqueous vapour. These are passed over a layer of deliquescents—such as chloride of calcium.

Delphinus (the Dolphin). One of the old Greek constellations. It succeeds Aquila in the sky. It has no stars larger than of the third magnitude. Its principal cluster of stars comes on the meridian, about a quarter of an hour after the chief cluster of Aquila.

Deneb. An old Arabian word used to signify the tail. It is employed sometimes to signify the place of a star in a constellation. Thus Deneb adige, the bright star in the swan's tail; Deneb elect, the bright star in the lion's tail (β Leonis). The name is now almost appropriated to this latter star. The words are Arabic.

Density. The density of a body is the degree of closeness between its particles. The term depends upon the hypothesis that the ultimate particles of matter have a weight, and, therefore, mass proportional to their bulk. The hypothesis may, or may not be true. It is probably not to be depended upon. The density of a body is considered to be the proportion of its mass to its bulk. The mass is considered to be the space which the really solid particles of the matter of a body occupy together, omitting all the intermediate spaces by which, in actual bodies, these are separated. If the particles of the mass be always of the same weight for their size, we may measure the density, or closeness of particles, by the proportion of the weight to the volume. Whether the theory be correct or not, this is the practical method used to determine the density. It coincides with the *specific gravity* of a body (*q.v.*)

Depression, Angle of. When we look at an object elevated above the horizon, the angle which the line, from it to our eye, makes with the horizon, is called the angle of elevation. This angle is just that made by that line, and the line in which a vertical plane through it would cut the horizon. If now we draw a line parallel to this latter line, the angle which it makes with our first line of direction is called the angle of depression. It is equal to the angle of elevation. It is the depression below his horizon at which a spectator at the object would see the observer.

Derivations. An algebraic term. The nature of it is explained under CALCULUS.

DEV

See the work of Arbogast.

Determinants. See POLYNOM.

Deviation, Angle of. See DIOPTRICS.

Deviation of the Line of the Vertical.

The figure of the earth is that of an ellipsoid, flattened at the poles. It is very nearly, but not quite, circular. Were the earth composed of homogeneous matter, the law of attraction which holds between all substances (of the inverse square of the distances) would require that at any point of the surface, a body, free to move in any direction, should stretch a string perpendicularly to this elliptical surface. The irregularities which present themselves in hills and hollows must be considered as not existing, and the surface which we take instead of the actual one would be the level at which the sea would stand if it could freely interpenetrate all our hills. If then the earth were homogeneous, or if it were made up of homogeneous layers all similar in form to the outer rim, though differing in physical character, the direction of a *plumb line* would be perpendicular to this surface.—Now, instead of this, we discover considerable deviations from such a law. According to it, the degrees of latitude would measure more, for example, as we proceed from the equatorial to the polar regions. We do not find this uniformly true. No doubt, there is a general tendency to this augmentation; but in certain cases it is temporarily disturbed, and that sometimes over a very large extent of country.—We have supposed that the earth is quite elliptical. May not the error of this supposition be enough to account for the deviations of which we speak? So far indeed it is. A vertical line is deflected from the true vertical sensibly, for instance, by the near presence of a very high mountain, as in Maskelyne's experiments on Schehallion. But it has been found that although this element of the problem be taken into account, it does not give a satisfactory reason for all the deviations. They sometimes are found in spots where no great elevation or depression of the surface is perceptible. There has not yet been offered more than a hypothetical explanation. That, however, accords so remarkably with the facts that very great confidence may be placed in it. It consists in the general statement, that the earth is *not* formed of homogeneous matter. It is certainly not formed of homogeneous layers. But, although we could only be warranted in assuming that a free weight will hang perpendicularly to the surface in those cases; it might still happen to do so, although the mass of the earth be heterogeneous. Geologists assert, however, that they can point out, in the character of the soil, and the nature of the neighbouring rocks, a sufficient cause, in the majority of cases, for the actual deviations. They even venture to predict from this deviation that the earth has, in some places, had its crust rent by certain fissures, which nevertheless they cannot yet reach,—and to tell us the direction in which these rents have been

DEW

made.—Whatever be the explanation, the fact that the *plumb line* deviates from the true perpendicular cannot be questioned. Very careful astronomical, and very expensive geodetical experiments are, however, necessary, before this deviation becomes sensible to observation.

Dew. There is, perhaps, no phenomenon recurring so frequently, and so manifest in its effects, that waited so long for a satisfactory explanation as this. — Before stating that explanation, we shall require to have, clearly before us, the various phenomena of dew, that we may understand the problem, and verify its solution. It will be interesting to trace in history the successive observations of these phenomena, and watch the theories to which each new observation gave rise.—The first, noted extensively, was the fact that dew falls almost solely on nights when the skies are cloudless, and the atmosphere at a low temperature. This coldness was found always to obtain, when dew had fallen. In point of fact, it is now found that the temperature must be considerably lower in a night when dew is formed, than it has been through the previous day; but this was not the form in which the statement was at first put. If we had a temperature of 120° Fahr. through the day, dew might, readily enough, be obtained at temperatures which we should call hot (60° or 70° Fahr.) These circumstances did not trouble the observers,—and they noted correctly that cold was necessary to the formation of dew. They found, however, almost simultaneously, that the sky required to be wholly, or in a great measure cloudless, and that either the stars or the moon must be distinctly visible. They conceived, then, that in the latter phenomenon the real cause was to be detected, and that the cold and the dew were *concomitant effects*. They supposed that the stars and the moon shed down a cold, and therefore, a humifying influence. They farther conceived this confirmed on observing that more dew falls at full moon than at any other time (which fact, by the way, they could not have observed properly); and they joined to this, their own crude notion that there is a peculiar chill in the lunar rays. Some transcendental ideas about the celestial purity of this stellar and lunar rain, completed the most ancient theory of dew.—It is worth while to point out how plausible this method of philosophizing at first sight may seem, and to warn the reader against similar attempts to explain phenomena. The ancients started with two facts, sufficiently observed, to be perfectly trustworthy. But, at that point, observation ceased. They raised hypotheses to account for the phenomena; but never thought of inquiring whether, though the explanation might serve, if these hypotheses were true, such were really to be found in *rerum natura*. They met with the success with which similar attempts—except in a very few, very rare instances—are sure to

DEW

most. The philosopher, if he wishes to arrive at truth, must always fall back upon Newton's modest motto, "*Hypotheses non fingo*."—Hence dew was conceived to fall from the sky; and the origin of that expression (found in all known languages) is to be sought in this plausible theory. Aristotle first called attention to the real amount of accurate knowledge upon the point, and added two new facts, viz.: that dew is never formed in windy weather, or on the summits of mountains. Both observations are to be taken within a limit. Dew is not formed by any means so readily under either of these circumstances. It is wrong to say that it is never found. These observations, however, were very valuable; and the use which Aristotle made of them was remarkable. His theory, forms an illustration, almost as striking as the former, of the manner in which carefully registered observations, cautiously reasoned upon, will lead us to new truths. He conjectured that dew was merely a discharge of vapour from the atmosphere. Vapour was water mingled with heat, which rose during the day time, or so long as it could obtain heat. Vapour, he imagines, will never rise high in the atmosphere, because it must lose its buoyant heat; conceiving heat to be some thin fluid which might become detached. Hence dew is most copious on low lying ground. Moreover, if vapour did rise high, the agitation of the upper air would dissipate it. Carrying out this idea, wind dissipates the vapour; on windy nights, therefore, dew will not be formed. The sun then, and not the moon or stars, is the cause of dew, because through its heat vapour is produced, and in its absence the cold comes.—This theory is, for that age, a most remarkable approximation. It still deals slightly in hypotheses; but every hypothesis, right or wrong, originates in some fact which renders it probable. Considering the uncertain state of the science of heat (reduced only in this century to a branch of mathematical physics); and the utter ignorance then prevalent concerning the mode of formation and the character of vapours; no result more close to the truth has probably ever been reached upon such a subject.—Aristotle's theory was, however, not appreciated in his own age, nor by his successors among the Greeks and Romans. The notion of the influence of moon and stars was too beautiful for a Greek to give up, and the Romans could not do better than follow the example of their masters. In the dark ages, physical inquiries were not favourably viewed, and even the schoolmen did not venture to support Aristotle's theory. The domain of the physical sciences was given over to the alchemists, and they could not, on any account, fail to support the claims of the moon and stars.—Baptista Porta rejected that part of Aristotle's theory in which lies its chief merit—the attribution of dew to condensed vapour—and tried to show that the air itself was condensed. He founded his conclusion on the existence of mois-

DEW

ture, and sometimes hoar frost, due to the congelation of what had been moisture, on the inside of a glass pane. This observation justified him, indeed, in rejecting the theory of the celestial influences. A similar conclusion was deduced from this other fact, that a bell glass placed over a plant to cover it from the frost, was copiously covered with dew in the inside, while very little appeared on the outside. The same conclusion was inferred from the circumstance, that plates of copper exposed during the night have only their *under* surfaces bedewed.—These facts served to explode completely the hypothesis of stellar influence: but a new one began to rise into notice. It was this,—the moisture with which bodies are bedewed, comes from the earth, and very copiously from plants; both which, under the influence of cold, exhale their moisture. Experiments were instituted as to the quantities of dew, obtained at different heights from the ground; and the result, with some variations certainly, seemed to show, that,—as might have been expected from this supposition—it forms more copiously at the surface of the earth than higher up in the air. In pursuing experiments tending further to establish this point, Muschenbroek stumbled upon a new phenomenon, hitherto quite unsuspected—that dew forms more copiously, upon some substances than upon others, placed in the same circumstances as to position and temperature of the surrounding air. He discovered, moreover, that it is formed, when it was very improbable that it could have risen from the ground.—It was now, therefore, held that dew does not fall from the sky; nor was it, at all events, necessary to its formation, that it should rise from the ground; and the readiest explanation which offered itself, was, that Aristotle's theory had been, after all, the true one, and that dew is produced by the condensation of vapour, held, as it were, in solution, by the air. According to this theory, moreover, phenomena, which, on close examination, one can see no reason for distinguishing from the formation of dew, received a natural explanation. When a mild spring comes after a severe winter, secluded passages, vaults, and other places concealed from the direct influence of the sun, and to which heat is very slowly conducted, become damp, and sometimes dripping with moisture.—If, therefore, this theory be correct, a deposition of dew will be obtained when we expose a very cold substance to the air of an ordinary room at any time. This testing experiment was tried, and succeeded admirably. Thus, if we have a tube with two pendulous bulbs at the end of it, in one of which is water as cold as we can obtain it, and around the other a cloth wrapped, which is moistened with a little ether, dew will be found upon the first bulb. The ether evaporates, and as heat is required to convert liquids into gases, it must have heat from some quarter. This it easily

DEW

procures from the water, which is cooled considerably, and on the outside of the bulb containing it dew is deposited. The phenomenon will be more evident if the latter bulb be blackened.—Philosophers now perceived that they were upon the point of discovering something, which, whether or not it might give a perfect explanation of the whole phenomena, would, at all events, cast considerable light on them. Several observers, therefore, gave great attention to the subject, and published very valuable experimental results. Prevost of Geneva, Six of Canterbury, and Leslie of Edinburgh, especially distinguished themselves. Their observations went, chiefly, to render indisputable the general truth of the observations already recorded—such as the invariable relative coldness of the body upon which dew forms; the progressive diminution in its amount, according as the bedewed substance is more and more removed from the earth's surface; and the effect which different substances exercise in modifying the quantities.—The next, and most important contribution was made by Dr. Wells, whose experiments, though perhaps not conducted with the greatest accuracy possible, nevertheless, were of the highest importance in establishing the theory of the subject. The essay which he published upon it, takes rank with the finest models of experimental inquiry after truth. His chief observations were, that the coldness of the surface bedewed, always *precedes* the formation of the moisture, and is not a consequence of it; and that dew is always most abundant when the air contains most vapour of water—other circumstances remaining the same.—Having thus reviewed the successive theories of dew, and seen by what prominent characteristics the phenomenon is distinguished, we now proceed to explain the theory at present universally admitted.—Water is found in the gaseous as in the liquid state. It is gaseous as steam, and as those vapours which, in a hot day, we see rising from rivers, or from a field on which rain has just fallen. In the atmosphere, therefore, two gases—dry air, and this aqueous vapour, exist together unmixed. According to Dalton's Law they ultimately each expand, occupying the same space as if the other did not exist; and there will always be a perfect intermixture if sufficient time be allowed. The first effect of this must be, to remove or carry up the aqueous vapour from the surface of all water. Now, it has been found that, at any temperature, water will evaporate entirely under whatever gaseous pressure, if means be provided for the removal of the aqueous vapour as it forms. If it be kept in a closed vessel, the stopper, even although not very close fitting, prevents that vapour from free passage into the atmosphere; and the aqueous vapour, therefore, which the water gives off, not being allowed to dissipate, forms a perfect barrier against

DEW

further evaporation. In a space filled with water and with air at a certain temperature, the water will evaporate to a *certain* extent, corresponding to the temperature; and if the vapour be kept from dissipating, it forms then a perfect cover against further volatilizing. But, in free space, unless there be an atmosphere already quite filled—to an extent corresponding to its temperature—with vapour, it will dissipate, according to the universal law of the dissipation of gases, into the higher atmosphere, where there is less vapour. The bar to further evaporation is then removed, and it continues until the adjacent space be saturated as far as its temperature will permit; it then ceases until the vapour shall have again partly disappeared, and so permits the formation of more. Air, at any temperature, will contain only *so much* of vapour of water—a fixed amount for each temperature. This amount increases with the temperature, and in an increasing ratio.—Suppose, now, that this process goes on for some time, say through a summer's day, when, as the temperature of the strata of air near the surface will be 70° or 80° Fahr. it will have a very great capacity for vapour of water. Evaporation will go on rapidly, as on a hot day we see that it does, and the atmosphere becomes filled with a very considerable amount of water in this state. Now, if any great cooling of the atmosphere takes place, it gets to be no longer capable of containing the same amount of vapour of water. If, for example, in the day we have chosen, as much vapour have passed into the air as would have saturated air at 60° Fahr. and if the air at night cool down to 40° Fahr. there is a considerable quantity of vapour which the air at this temperature cannot hold. This excess is condensed and deposited in the form of dew.—So far, this is precisely Aristotle's theory, with some more definite understanding of the cause of the condensation, and of the other results by which it is preceded; but there is yet one point requiring explanation, and that is, the method in which the cold is produced. The mere absence of the sun, one cannot expect to produce cold. That causes a cessation of the increase of heat which had been going on. During the presence of the sun, in the afternoon, and at sunset, indeed, there is this diminution of temperature while the sun is present. The theory of radiant heat which M. Prevost started, and which is now so conclusively established, gives a full explanation of the phenomenon; and for the first statement of that explanation we are indebted to Dr. Wells.—During the day time, heat is transmitted from the sun to the earth. Wherever we have two bodies of different temperatures, there is a radiation of heat from the hotter to the colder. Now, the sun is a body at a very high temperature, and the earth at a moderate heat. During the day, then, those parts of the earth to which it is day, being exposed to the

DEW

sun, absorb quantities of radiant heat. The air also absorbs it. It also is a body exposed to the sun; though one which both radiates, and absorbs much slower than the earth. Hence it also is heated during the day time. According to this statement of the case, however, the upper air would have the highest temperature. Two circumstances prevent this. The very rarity of the upper air—the property in which it is likest heated air—prevents it from heating by radiation. It absorbs less rapidly the heat from the sun. The earth absorbs that, most rapidly of all, and as the air can conduct heat, it gives a portion of its heat to the stratum lying upon it. That stratum becoming heated, rises, and a new stratum is deposited to be again heated, and again to rise. There is thus a tolerable uniformity of temperature produced near the surface.—Next, we have, on a clear night the earth laid open to the stars and to the interstellar spaces. We do not, by any means know the temperature of the first, but they are too far away, for their radiant heat, any more than their light, to be able to exercise considerable effect on us. The earth, then, and the interstellar spaces are exposed, one to the other. Now, we know that the temperature of the latter is at least 100° Fahr. below zero, while the surface of the earth, having just absorbed an amount of radiant heat from the sun, is perhaps 50° or 60° Fahr. above it. Radiation commences immediately, and if uninterrupted, would continue until the temperatures were equalized. The effect of this radiation, while it lasts, is to lower the temperature very materially at the earth's surface. Let us consider the state of the air during this period. It is not affected by the transmission of the radiant heat from the earth outwards, to space: but it serves itself to radiate some heat away. It does this so slowly, however, that the effect in cooling it from this cause, like the heating effect from the same, during the day, is comparatively insignificant. Now, as then, the chief effect is produced by the conduction of heat from the air to the ground. By this, however, the stratum of air next the ground, is cooled, and it does not rise to give place to another. The cooling process goes on, therefore, until the stratum is equal in temperature to the ground, or rather, its temperature continues to diminish indefinitely, along with that of the ground. Now, during the day, vapour has been collecting in this stratum, perhaps not quite up to its saturated point, but generally very near that. Hence, when this cooling lowers the temperature, the air is no longer able to retain its vapour; and moisture is detached and deposited as dew.—By conduction, the air above also cools, and dew gradually separates from it. As air, however, very slowly conducts heat across it; except when the heat puts the heated air in motion (see CONVECTION), this process is very slow. Hence very little moisture is detached from the

DEW

upper portion of the atmosphere. But, it may be asked, does not dew deposit upon bodies at considerable elevations from the earth's surface—elevations that are yet such, that if dew fell from them on the earth, there would be a shower of dew? In answer, let it be noted, in the first place, that the layer of air in immediate contact with the earth does not remain constantly so, through the night, in virtue of its superior heaviness. It is well known that when vapour is formed from water, a considerable quantity of heat becomes latent; and when, on the other hand, condensation takes place, heat is evolved. When, therefore, dew begins to separate from the bottom layer, it receives a sudden accession of heat from the condensed vapour, which lightens it, and carries it upward. Thus, a new layer, more saturated with vapour than the former one, after its loss, descends by the superior weight due to its lower temperature, and takes its place. Therefore, there is no necessity for a *fall* of dew in any case. Yet dew seems to separate, nevertheless at considerable elevations, though less copiously than at the surface. It only separates, however, when a body which radiates heat well is placed at these heights, and the quantity in which it separates depends upon this faculty of the body. This explains Muschenbroek's observation of the different capacities of different substances for dew. A good radiator becomes rapidly cold, and dew is rapidly formed on its surface; while a bad radiator in the immediate neighbourhood remains unaffected. Thus, a slip of tin foil pasted upon a sheet of glass, will remain perfectly dry while the rest of the glass is profusely covered with dew. This property may be strikingly shown by experiments, which, founding upon it, describe figures and letters in dew, on plates on which glass and tin foil have been suitably arranged. The exquisite little figures made by dew, and especially by hoar frost, on window panes, depend upon this principle. The glass, from various causes, does not radiate uniformly.—According to this property, therefore, no dew separates in free air, at any considerable elevations—unless a very good radiator have been placed there.—It still remains to be explained why, in this last named case, dew is never formed so copiously as at the earth's surface. This partly arises from convection of air. If we place a body which can become cold by radiation, at a considerable height, it renders the layer of air in immediate contact with it also cold, and so, heavier than the air between the earth and it, which is but little cooled by radiation, and, if at some height from the earth, not very much by conduction. This air, therefore, falls, and as at the side, it is unsupported, it falls away from the cold plate, leaving warmer and lighter air pressing up to supply its place. If indeed the plate be perfectly horizontal, the air at the surface of it would remain, and dew would be produced; but it is not easy to adjust it so,

DEW

and the least inclination will allow the heavy air to fall away, and prevent dew from being formed in considerable quantities, if at all. Hence dew will more copiously form at the bottom of a vessel so situate than in any other position. Besides this, however, there is, generally speaking, not so much vapour of water present in such a case. The vapour which has risen through the day, requires time to interpenetrate the air. If time be given, Dalton's law will be completely fulfilled; but it is not given, in the course of a day, when new disturbance is added, every minute, by new vapour forming at the surface. Hence at certain heights there is less moisture present in the air than at the surface; and so the radiating body must be cooled lower still, before dew is formed. Dew will therefore commence to form later in the upper air, from convection, and the lesser supply of aqueous vapour; and the same causes will evidently cause less of it to be formed there, in the most favourable case, than at the ground.—Two other phenomena noted in our historical sketch are explained in the same way. Dew is more copiously formed on the inside of a bell glass than on the outside, and on the lower side of a copper plate, held at a moderate distance from the earth. In both cases convection prevents a copious deposit on the upper surface;—and, in both instances, the interval between the ground and the plates is small enough for the whole air included in that interval to be cooled below the point of saturation; and therefore for dew to be formed even at its loftiest places. This is accomplished chiefly through that conducting power of the copper or glass, which takes the supplies of heat they continue to dissipate, from their whole mass, lower as well as upper. This must draw its supplies, in turn, from the air which must constantly descend as it cools, until all of it has passed the point of saturation (dew point).—When the cooling goes on rapidly, the vapour deposited on dew, finally solidifies into *hoar frost*. The two phenomena rest upon the same principles, for their explanation. While dew is beneficial to plants, hoar frost is eminently destructive. Hence gardeners seek to prevent such a refrigeration, as would cause hoar frost. Their method is very simple. They spread mattings over their plants, and protect them from the sky—precisely as running water is protected by ice. See CONGELATION. The radiation thus takes place between the plants and the matting, rather than between them and the sky. The matting radiates to the sky, and loses its own heat rapidly; but, at first, its temperature is not far below that of the plants, which therefore transmit very little heat to it. Even when the matting has become frozen, the temperature is much higher than that of interstellar space; and the radiation from the plants is not, therefore, nearly so violent. If the process were continued, indeed, the three temperatures would be perfectly equalized, but the

DEW

return of day prevents that. The matting serves merely to retard the equalization of the temperatures of the sky and ground, by interposing. Sometimes there is not even dew formed in this way; but very seldom, except in the severest weather, is hoar frost formed.—The same principle explains another phenomenon, which we noted in connection with the subject. Dew is very seldom formed except in a clear sky. When the sky is clear there is free radiation to the interstellar spaces. When, on the contrary, there are clouds in the sky, the radiation is from them to the sky, and from the ground to them. To be perfectly correct, indeed, we should say that there is radiation from the ground to the sky, but the moment that the temperature of the earth gets lower than that of the portion of the cloud turned towards it, a counter radiation sets in from the cloud; supplying the loss from the radiation to the sky, and permitting only a very slight decrease of the temperature from that point. Radiation from the earth to the spaces is, moreover, just as in the matting, nearly intercepted by the interposed screen. The worse conductors such bodies are, the better will they serve the purpose of protecting the earth, and it would not be easy to find a worse conductor than the clouds.—We do not enter into a detailed explanation of how the theory accounts for all the different phenomena. In a windy night dew is seldom deposited. No one layer of air is kept in contact with the earth long enough to cool, as may readily be seen. The fact that it is formed most copiously in valleys, and least on pointed hill tops, will suggest its own explanation, in the principle of convection; and other such phenomena may safely be left to the ingenuity of the reader. It is impossible to conclude, however, without pointing out the very striking protection which the formation of dew affords against those night frosts, which, without it, would totally destroy all our present vegetation. The moment a particle of vapour is condensed into dew, the heat which had been required to preserve the gaseous state is disengaged and set free. This heat partly serves to keep up the supply of air, well saturated with vapour, by driving up the layer which has been just used, and thus prepares to repeat its effects; and partly goes to the earth, where it serves to supply the loss by radiant heat, and to retard the progress of its refrigeration. When the new, well saturated layer descends, this process is repeated; and thus a regular supply from the heat given in the day, to form vapour of water, is made to moderate the rapidity with which, according to the laws of heat, the earth would cool in the night time. Instances of this compensating character are found throughout His works. There is no waste of energy permitted; and that which seems uselessly squandered during the day, proves to have been only gathered up for indispensable service in the ensuing night.

DIA

Diacanestic Curve. A species of the canstic curve (see CAUSTIC) formed by refraction. The properly canstic curve formed by reflection, is termed also catacanstic.—When a number of rays come from a luminous point, such as A, and enter upon a rarer or denser medium, whose border is such as B C D E F, they do not proceed in the direction A C, A D, &c., but are refracted in the directions C M, D M, E M, F M. Now,

imagine A C and A D to be lines infinitely near, the one to the other, their refracted rays C M and D M will come to cut, generally, in a point, like M. If we further imagine all the innumerable rays refracted from the curve to be so grouped in pairs, of those nearest one another, we obtain a series of points of junction, like M, which will present together the appearance of a curve, described by a dotting instrument, and if we imagine the rays infinitely near, each successive point of junction will be infinitely near the preceding, so that we obtain a complete curved line—according to the description of a line as made up of an unlimited number of points, laid infinitely close, the one to the other.—This curved line, represented in the figure by O M N, is called the diacanestic curve.—In order to find the diacanestic curve mathematically, in any definite circumstances, we require to remember that the sines of the angle of the incident ray, and of the angle of the refracted ray, with a perpendicular to the refracting surface, bear a constant ratio, when we pass from one medium to another.

Electrometer. A sort of electroscope invented by M. Rousséau, where the dry pile is made to measure electrical force. The instrument is of use in teaching us the conducting power of bodies as regards electricity. It is sometimes made use of in commerce for measuring the purity of oils.

Diametral. In plane figures any line drawn from one corner of the figure to any other, not on the same side as the first. In polyhedrons, it is the line joining two angles whose vertices are not on one plane side. The diameter of a circle is sometimes called its diagonal. The number of diagonals capable of being drawn from any one angle in a polygon is the same as the number of sides wanting three.

Dialling. The sun dial consists merely of a straight rod firmly attached to a plane surface, along which the sun throws its shadow at the different hours of the day, in such a way that we may know the time of day by the position of the shadow. As the sun is not at the same spot in the sky at the same hour of the day in

DIA

different times of the year, it is manifest that the only sun dial of any value, will be one which will throw the different hour shadows constantly in the same direction; and every dial will not do this. The straight rod requires, in fact, to be pointed towards the pole star of the place. Then, as the sun's diurnal revolution round the pole is uniform—(with slight variations that are neglected in dialling,) the place of the sun at different hours of the day, will be, at all times of the year, in the same hour circle; and the shadow of a line towards the pole, from any object anywhere on the circumference of that circle, will differ only in magnitude, not in direction. Each hour will therefore be indicated by a shadow line along it all the year through.—Dials are usually constructed with the plane (dial plate) horizontal, the rod (gnomon) always being turned towards the pole. In either case, the shadows for the different hours are not at equal angular distances. The hour circles, and therefore the planes of shadow are. The reader will at once comprehend the reason by cutting an orange through its centre obliquely to its axis. Each lith is of equal size, but the exposed surface of each on the freshly cut circle will not be so.—If the orange were cut perpendicularly to its axis, they would be so. If in different directions, oblique, to its axis, the relative spaces for the liths would be different. Hence, as the horizontal planes of each place are inclined to those of any other, and the direction of the axis is constant, the graduation of one horizontal (or vertical) dial would only be adapted to the one place where it might be used. If the dial plate be made, instead, perpendicular to the direction towards the pole, the graduation will be perfectly uniform and regular at every place—as much for one hour as for any other. Hence the principle of the universal dial. It is merely a rod through the middle of a circular disc whose plane is perpendicular to it, graduated uniformly, into 24 divisions. Its use in any place presupposes this, and only this—a distinct knowledge of the direction of the north pole from the spectator.

Diamagnetic. A term introduced by Faraday in connection with his discovery of the influence of magnetic force upon all bodies. By a diamagnetic is meant any substance which, when placed in a field of magnetic force, does not conduct itself in the same way as the magnetic bodies, Iron, Nickel, and Cobalt. Before Faraday's discovery in 1845, the known properties of almost all the diamagnetics in relation to magnetic action were merely negative. It was known, indeed, long previously, that masses of Bismuth and Antimony act in a remarkable way upon a neighbouring magnet, repelling the nearest pole, instead of attracting it as Iron does; but this remained an isolated and barren fact, and seems to have received little attention till it was reduced by Faraday's discovery to a case of

general magnetic action. In the present article a statement will be given of some of the more important facts brought out by this discovery,—general and theoretical considerations will be reserved for the articles on **MAGNETISM** and **MAGNETIC INDUCTION**. It was in the course of experiment already referred to under **CIRCULAR MAGNETIC POLARIZATION** that Faraday first observed the new mechanical action of magnets upon bodies placed in the field of force. A bar of heavy glass was suspended centrally between the poles of a powerful horse-shoe electro-magnet. When the force of the magnet was developed, the bar no longer swung indifferently, but moved round its point of suspension into a direction at right angles to the lines of force, or at right angles to the direction that would be taken by a bar of soft iron placed in the same part of the field. Round this position the bar made a few vibrations, and finally settled in it. If displaced from it by the hand, it returned to it and settled as before, showing that this position of the bar, which Faraday calls the equatorial, was a position of stable equilibrium. When the bar was placed originally, at rest, in the axial position, or in the position of stable equilibrium of an iron bar, it did not move out of this position under the action of the magnet; but if displaced a little in either direction it moved on into the equatorial position and settled there as before; showing that the axial is a position of unstable equilibrium. It was observed further, that if the bar was placed near one of the poles, it was not only directed round its point of suspension, as above-mentioned, but was also repelled as a whole by the nearest pole, the centre of gravity of the bar sensibly receding from that pole, and so remaining while the magnet was retained excited. The effects are simplified by the employment of one electro-magnetic pole instead of two. In this case, the bar is always repelled by the pole in the direction of the lines of magnetic force passing through it; and it moves at the same time into a position perpendicular to the lines of force. The effects are further simplified by using a cube or ball of heavy glass instead of an oblong bar. When such a body is acted on by one pole, it moves constantly outwards in the direction of the lines of magnetic force. When subjected to the action of two poles, the effects are more complex; but there is a simple law that explains them all. It is this, that a particle of heavy glass or other diamagnetic tends constantly to move outwards, or into the positions of weakest magnetic action. The directive tendency of an oblong diamagnetic across the lines of force when one or two poles are employed can be easily accounted for by this law. It is a simple result of the joint tendency of all the particles towards the positions of weakest force. The property of being repelled by magnetic poles is not peculiar to heavy glass; it is on the contrary common to the most of natural and artificial bodies. It may be said

without exception, that every known substance, when subjected to electro-magnetic forces of sufficient power, will give some positive result, either of the magnetic or the diamagnetic character. And it is in comparatively few cases that the results are of the common magnetic kind presented by iron and nickel. Faraday himself tested a great number of bodies taken from all classes, amorphous and crystalline, liquid and solid, organic and inorganic. In this examination, the liquids were experimented on by being enclosed in glass tubes, the action of the glass under the magnetic forces being taken into account. Some of the results may be stated. Transparent bodies were the first examined, as was natural in the circumstances of the discovery. And it was found that even such transparent bodies as the singly and doubly refracting crystals, whose magnetic rotatory action upon light is too feeble to be observed, are yet subjected to directive and repulsive actions by magnetic poles in their neighbourhood, as other diamagnetics are. Of opaque bodies again, whose condition under magnetic action could not be tested by means of light, some are found to act very powerfully. Phosphorus may be mentioned as equal, if not superior in its mechanical indications, to heavy glass. Sulphur and India rubber are also well directed and repelled. Among liquids, alcohol and ether are evidently diamagnetic, and water still more so. Of organic bodies, the most are clearly diamagnetic. Wood, starch, sugar, leather, beef, mutton, apple, bread, blood are instances: they are all repelled by the magnetic poles, and, when in oblong volumes, directed equatorially. With regard to the gases, Faraday obtained no positive result in the first series of his experiments in this field. It was discovered, however, by Bancalari, that flames are mechanically affected by magnetic forces; and the subject was resumed by Faraday and other philosophers with success. It was found in the first place, that a current of heated air ascending between the poles of an electro-magnet conducts itself as a diamagnetic, separating under the magnetic action into two streams which ascend on different sides of the axial line. On the other hand, a descending current of cold air is not divided under the action of the poles, but keeps to the axial line. A descending stream of oxygen acts as a powerful magnetic body; if its proper line of descent is on either side of the axial line, its direction is changed by the action of the magnet, so as to intersect the latter line. All the other gases, when treated similarly, are found to be diamagnetic, with the exception, perhaps, of nitrous gas. To render the effects of the magnetic action more evident, Faraday enclosed the gases in soap-bubbles, and set them afloat in the magnetic field; and this test was found to be very delicate. Oxygen in these circumstances was powerfully attracted, and the other gases gave results in accordance with previous experi-

ments. By employing glass tubes as the envelopes of the gases, in connection with a delicate torsion-balance, Faraday has even compared the gases magnetically with each other, and with themselves in different states of density and temperature. The contrast brought out by this method between the two principal components of our atmosphere is very interesting, and highly important also from its bearings on the Theory of Terrestrial Magnetism. The magnetic power of oxygen suffers evident diminution by a diminution of density, and also by an increase of temperature; though the gas cannot be rarefied or heated to such an extent as to lose all magnetic power. Nitrogen, on the other hand, which is a diamagnetic, undergoes no sensible change in its magnetic relations by the utmost attainable changes in density and temperature. In this brief view of the natural bodies in their magnetic relations, we have to refer finally to the metals. Iron, nickel, and cobalt, have been long known as magnetic metals, though the second is far inferior in power to iron. To these metals Faraday has added the following,—platinum, palladium, titanium, manganese, cerium, chromium, and perhaps osmium. Some of these are inferred to be magnetic from direct observation of their actions in the field of force, while the character of others has been determined by the actions of their chemical compounds. The rest of the metals appear to be non-magnetic in the common sense of the term. They are found to be all subject to the influence of the magnetic force, and they produce the same general effects as heavy glass and the other diamagnetics already referred to. The repulsive forces are manifested on the diamagnetic metals in very different degrees. Some of the metals, as gold, copper, silver, are inferior as diamagnetics even to water; and with the exceptions of antimony and bismuth, they are all inferior to heavy glass. The last mentioned metal has been characterized by Faraday as one of the best substances for the exhibition of the entire diamagnetic phenomena of the mechanical kind. The conduct of the various compounds of the metals under magnetic action has been studied with great attention. We may merely state the general law which has been arrived at upon this point by a very extensive induction;—that the decidedly magnetic and the decidedly diamagnetic metals preserve their magnetic characters throughout all changes of mixture and chemical composition and solution. By inference from this law, Faraday has determined the magnetic character of some of the metals, whose indications in the magnetic field could not be depended upon. It need hardly be observed that it is not meant by the above statement, that a solution of salt of iron for example, will act evidently under magnetic force in the same way as iron itself does; for it may or may not so act according to circumstances. The magnetic action of a mix-

ture or chemical compound of different matters is the resultant of the actions of all its constituent parts; and the law is, that the action of each part is proper in kind and quantity to the part itself, and independent of the circumstances of mixture and chemical composition into which the part may enter. A solution of iron then will be magnetic or diamagnetic according to the strength of the solution, that is, according to the proportion of water or other diamagnetic matter with which it is diluted. It is interesting to observe generally in this connection that the magnetic and diamagnetic properties of the parts of any mixed body, while they oppose each other in their effects, appear to interfere in no degree with each other in their proper actions. The delicacy of the experimental researches that have been conducted in this field is well illustrated by the phenomena of mixed bodies. Glass in a pure state is evidently diamagnetic, but in the common forms of green-bottle and crown it is as evidently magnetic, in virtue of the small quantity of iron present in its mass. Wood in a pure state is diamagnetic; but to obtain a chip that will conduct itself as a magnetic body we have only to detach it with a common knife. Common paper again has been sometimes found to possess magnetic properties; and the fact has been explained by the contact of iron with the paper in the process of manufacture. In the previous part of this article, bodies have been considered in their magnetic relations without reference to the *enveloping matter*, and they have been spoken of as absolutely magnetic or diamagnetic. This view has preserved us from unnecessary complication in the statement of elementary facts, but it now requires an important correction. The conduct of a body in the magnetic field depends as much in fact upon the nature of the enveloping matter as upon the nature of the body itself. As a simple instance:—there are certain substances which set equatorially and are repelled in air, while in water they set axially and are attracted; in other terms, they act as diamagnetics in a magnetic field which is occupied by air, while, in the same part of a precisely similar field which is occupied by water, they act as magnetics. Phenomena of the same kind are presented by other media. There are certain remarkable experiments of Faraday's that are worthy of notice in this connection. Glass tubes were filled with solutions of iron of different strengths, and were hermetically sealed. Vessels were also filled with the solutions, and placed successively in the magnetic field. The tubes in succession were immersed moveably in the vessels when occupying the field of force; and though all the tubes were magnetic they sometimes pointed equatorially. The phenomena presented this constant law;—that if the solution in the tube were stronger than that which enveloped it, the tube conducted itself as a magnetic body; if on the other hand, the in-

DIA

ternal solution were the weaker, the tube was repelled and directed equatorially, and could be distinguished in no way from a diamagnetic. These facts have an evident bearing upon the nature of the distinction between bodies as magnetic and diamagnetic. But we consider them at present merely with an inductive view, and without reference to theoretical questions that may be raised in connection with them. From the above statements it is evident, that we cannot properly speak of a body as magnetic or diamagnetic without reference to the medium in which it is placed. But in practice we can dispense with the reference without any danger of mistake, by agreeing that where no medium is mentioned the air is understood. After this, the action of media as far as determined may be easily described. A magnetic body will act as a magnetic in every diamagnetic medium, and in every medium of less magnetic power than itself, but as a diamagnetic in every medium of greater magnetic power. A diamagnetic will act as a diamagnetic in every magnetic medium, and in every medium of less diamagnetic power than itself; but as a magnetic in every medium of greater diamagnetic power than itself. In conclusion, we may observe, that these and other facts are powerfully in favour of the idea, that bodies differ from one another as magnetic and diamagnetic only in virtue of the difference of degrees in which they possess the one common magnetic property. And that therefore a mass of bismuth or heavy glass recedes from the magnetic pole, not because of a repulsive action of the pole upon the diamagnetic, but because of a greater attraction exerted upon the surrounding medium: just as smoke ascends in air, and light solids in water, in opposition to the proper attractions exerted upon them. This view was stated by Faraday as probably the true one, in connection with his singular experiments on solutions of iron already described; but he has seen reason to question it, and to speak of the movements of diamagnetics in the field of force as due to a proper repulsive action of the poles, an action therefore entirely different from the common and long-known action of magnetic force. Whatever view be taken upon this point, there can be only one opinion as to the importance of the discovery of "the new magnetic condition." Magnetic science has received from it a very great extension. Those subtle forces that were formerly known only as exerted upon iron and two other metals are now recognized as acting effectively upon all bodies, and as exercising, in all probability most important functions in various departments of the great system of nature.

Diaphanometer. An instrument proposed and employed by Saussure for measuring the transparency of the air. It consisted of a number of circles of different diameters drawn on white grounds. Having placed these beside each other, the observer recedes until the smaller

DIA

circle becomes invisible, and measures the distance. Then he recedes until a larger circle becomes likewise invisible, and again measures the distance. If the air be perfectly transparent these distances ought to be exactly proportional to the diameters of the circles; if they are not, the difference is due to the absorption of the luminous rays, or to the imperfect transparency of the atmosphere.

Diaphanous. Transparent. See TRANSPARENCY.

Diathermanism; Athermanism; Thermanism. Reference has already been made to the phenomena indicated by the foregoing terms, in article ABSORPTION. The Inquirer who first carefully surveyed them was Melloni. Desiring to ascertain according to what laws radiant heat either passes through different bodies, or is absorbed by them, this philosopher first investigated how much of the incident heat was neither radiated nor absorbed, but rejected or sent back by way of *reflexion*. This—it turns out—whatever be the plate on which it falls, is $\frac{1}{10}$ of the whole; so that of 100 rays falling on the plate, only 92.8 require to be accounted for by transmission and absorption. This preliminary established, Melloni proceeded to evolve, by a long and elaborate series of ingenious experiments, how far the transmission of radiant heat, through plates, is affected by the *substances* of the plate, by its *thickness*, and by the *source*, and *degree of the heat* incident on it. Different substances vary exceedingly in their power to transmit radiant heat; for instance, *rock salt* transmits the whole; *alum*, scarcely any rays; *black glass*, and *smoked quartz*, transmit abundantly, notwithstanding their opacity. In general, the quantity transmitted varies with the thickness of the plate; but this only up to a certain limit; for after the plate has reached a certain thickness, that thickness may be further increased without lessening the amount of transmitted heat. This amount varies also with the temperature of the source of the rays: sources of low temperature appearing to contain a smaller proportion of transmissible rays: and Melloni has reached the further and definite conclusion, that *the least refrangible calorific rays of the solar spectrum are likewise the least transmissible*. These phenomena, regarded as a whole, manifestly point to the conclusion, that the action of bodies in transmitting heat, is quite analogous to the action of transparent or coloured media in transmitting *light*. The characteristic of coloured media, in this respect, is, that they exert an absorbing power, by preference, over a certain colour: for instance, if a glass plate permits the red rays only to pass, another similar plate, behind it, will not absorb the ray transmitted by the first, whilst a violet plate would impede or absorb the whole of it; or, if the coloured plate, instead of transmitting a simple ray, transmitted a compound tint, the results of

DIA

the interposition of an additional plate would be entirely similar, although analyzed with some difficulty. Observe now the phenomena in question. As soon as radiant heat has passed through a certain thickness of any substance capable of transmitting it, the heat becomes *purified* or *thermanized* in relation to that substance: not only does the ray traverse it more easily, but it is not subject to any further absorption on the part of the same substance. If, however, a second substance be brought to act on the ray thus *thermanized*, quite a different result ensues; rock crystal, for instance, acts in absorbing heat that has passed through glass, just as if the heat was in its natural state, or not *thermanized* at all; that is, it absorbs a large portion of it. Glass acts in the same way on heat that has passed through rock crystal: these two substances, therefore, are quite in the same position with regard to radiant heat, as two differently coloured glasses are, with regard to light. Now, it is this peculiar property of substances—a property enabling them to *select*, as it were, the elements of the ray of heat which they claim to absorb, that Melloni designates as their *diathermancy*; or, as he rather might have called it, their *thermancy*: the substances thus *selecting*, are *thermanizing* substances; and the heat modified by the action of such substances is said to have been *thermanized* with respect to them. Rock salt, for instance, is *diathermanous*, but not *thermanizing*, because it transmits all the incident rays; and the heat which passes through it is not *thermanized*, but natural heat, possessing all its original elements.—As to the influence of different sources of heat, it must be kept in mind that every source does not necessarily give out all the elements of natural heat; just as there are coloured flames, there probably are sources of radiant heat which send out defective heat, a heat already *thermanized*: neither must it be concluded that the degree of the temperature of the source, necessarily determines that its heat contains fewer absorbable rays; for Melloni has recently established that rock salt properly smoked by the flame of a candle, absorbs a proportion of heat which is greater, the higher the temperature of its source.

Diathermanous. A body that transmits radiant heat is called *diathermanous*; *athermanous*, if it transmits none.

Dichroism. The optical phenomenon thus designated is peculiar and complex. It may be briefly described as follows.—Every coloured doubly-refracting crystal on which a vertical beam falls, may be considered as permitting to pass through it, in the *first* place, a certain quantity of coloured light, *not polarized*; which light passes freely in all directions, without reference to the optical axis, or axes of the crystal,—the crystal acting in regard to it much like any other coloured medium; and in the *second* place, a certain quantity of light polar-

DIF

ized according to Biot's law for biaxial crystals. This latter quantity of light being necessarily variable, according as one transmits polarized light through the crystal or analyzes that light transmitted by a doubly refracting apparatus, there results—when the variable light is itself coloured—a numerous series of shades of colour; from that of the non-polarized light when it passes alone, to that formed by the mixture of the colour of the non-polarized light with the colour of the whole polarized light. If attention is paid to these extreme shades only, the phenomenon is termed *dichroism*: but as there are many intervening shades, every doubly refracting coloured crystal with one or two axes, manifests a veritable *polychroism*.

Dichroscopic Microscope. See MICROSCOPE.

Dielectric. Any substance through or across which the electric forces are acting. Thus, the air between two electrified surfaces is a dielectric, the wall of a charged Leyden jar, and the insulating plate of a charged condenser are also dielectrics: for the electric forces act through these substances, and produce sensible effects at their terminating surfaces. The importance of the functions of the dielectric in all the electric actions is the most distinguishing feature of Faraday's Theory as contrasted with the old Theory of Electric Fluids. Thus, in explanation of the inductive action of one charged conductor upon another, the dielectric was altogether ignored in the old theory, except as insulating the fluids and as occupying a certain extent of space. Faraday on the other hand explains the ordinary inductive action by the supposition of a system of actions among the particles of the matter that lies between the charged surfaces. In this way the dielectric becomes of essential importance in explanation of the entire phenomena of induction. Further, he regards the peculiar inductive state of the particles of the dielectric as an essential condition of charge itself. It will be evident that if these suppositions are true, the dielectric has an active influence of the most essential kind in all the actions of conduction and discharge. So that, in short, whenever we have charge or discharge in any form and in any intensity, the action of the dielectric is supposed to enter as an essential condition of the phenomena. These ideas are simply suggested and powerfully supported by experiment; and if they have the disadvantage of vagueness, it is because they are not more definite than sound reasoning from existing experimental data would warrant. They have the great merit of linking together the varied phenomena of electricity in a harmonious whole, and of thus fulfilling, to a certain extent, the principal office of a Theory. For a statement of these theoretical points, and for a description of the specific properties of dielectrics, see INDUCTION.

Difference: Differences: Calculus of

Finite Differences. The simple meaning of the arithmetical word *difference*,—viz.: the excess of a larger quantity over a smaller—is virtually lost, in reference to the same term, when used in the higher branches of the Mathematical Analysis. We shall attempt very briefly to convey some notion of its nature and comprehensiveness, as thus employed. Suppose that any series of numbers exists, whose terms, however irregular they may appear, are held together by a certain law,—the character of that law will evince itself by the fact, that if the differences of the numbers be first taken, the differences of these differences next, then the differences of these second differences, &c., we shall arrive at a term or order of differences whose difference is 0. For instance, take the following numbers, and find the successive differences:—

Series.....	43	47	53	61	71	83, &c.
First difference....	4	6	8	10	12	
Second difference..	2	2	2	2		
Third difference...	0	0	0			

Now, the nature of the law of the series written down above is expressed by the fact that its *third* differences are *Zero*: and the terms of any series or set of numbers may be calculated, if we know the first term and a few characteristic facts regarding their differences. In the series just written down, it would suffice to know the terms 43, 4, 2, and 0, to enable any one to write out the whole apparently irregular series. It is on the ground of this principle that Mr. Babbage's Machine, and all others of a like kind, can compute extensive tables, such as tables of Logarithms (see ENGINE, CALCULATING).—The whole of this subject has grown into the *Calculus of Finite Differences*, an important and elaborate branch of the modern Analysis; first proposed by Dr. Brook Taylor, under the name of the *Method of Increments*. Of course, it is impossible to enter here, on consideration of the processes of this Calculus; but a few remarks are needed to enable the student to distinguish it clearly from that true Transcendental Analysis—viz. the method of *Infinitesimals*. It is not possible to regard the method of Finite differences as at all related to the great conception of Leibnitz. The fundamental conception of Taylor is the following—viz.: it is required to detect what changes will pass on a function, if to its variable *a definite increment be added*. Now, this definite increment can differ from the original variable only in relative magnitude: it is a quantity altogether *of the same sort as the variable*; and it is difficult to see in what way—by taking it as an intermediate quantity—we can establish equations that define the variable, more easily, than might be done by working with the variable itself. The immense facility, and therefore the immense advantage of the Transcendental Calculus, lies in the very fact, that the increments employed are quantities *differing in nature from the original variable*—that, in

fact, they are *infinitesimals*; and therefore that we can neglect higher powers of them in comparison with lower powers, and higher differentials in comparison with lower ones, without, as has been shown (see CALCULUS), endangering the accuracy of the equation. Lagrange has pointed out this radical distinction, with the power usual to him: and he has shown that the pretended analogy sometimes asserted between the *Calculus of Differences* and the *Infinitesimal Calculus*, has therefore no existence; and that formulæ of the former calculus can never furnish, *as mere particular cases*, formulæ belonging to the latter, seeing that their nature is essentially distinct.—But though the Calculus of Finite Differences has thus no pretension to take rank with the Infinitesimal Calculus, and is comparatively powerless in the field of the triumphs of the latter, it is impossible to overlook its grasp and importance as a branch of pure Algebra. Of the whole doctrine of *Series*, it is undisputed Master; and it has given birth to the superb *Theory of Generating Functions* of Laplace. We also owe to it that valuable theory of *Periodic and Discontinuous Functions*, first introduced by Euler, and afterwards so greatly advanced by Fourier. See FUNCTIONS.

Differential; Derivative; Fluxion. See CALCULUS.

Diffraction of Light; Inflection. The very remarkable and puzzling phenomena designated by the foregoing terms, have been known since the time of Grimaldi, who also made the earliest attempt to explain them, in 1665. They consist of curious appearances connected with the shadows of opaque objects, when these are placed within rays diverging from a simple line or point. For instance, if a small lens or burning glass of short focus be fitted into a hole in a shutter, it will concentrate the light passing through it, in a bright point; and from that point rays will diverge through the dark room. An opaque object placed within these rays will, of course, cast a shadow, on any screen; but instead of the *real* shadow corresponding with what may be termed the *geometrical* one, its edge will be found quite indefinite,—certain curious tints in the form of *fringes* of colour, or of alternating dark and light, extending to some distance and running parallel to that edge. These curious appearances were attributed by Newton (who held that theory of light known as the *Theory of Emission*,) to certain molecular attractions and repulsions between the *matter* of the rays, and the edge of the opaque body: but, irrespective of minor, although decisive objections, the following classical experiment of Fresnel's—by which appearances *of the same nature*, are produced under circumstances totally different—gave this explanation its death-blow. Having arranged a lens, Δ , so that rays of light concentrated at its focus, might thence diverge into a dark room, he placed opposite to it two plane metallic

DIF

where x and x' , in the way shown in fig. 1. These mirrors, on receiving the rays FG and FH , reflect them downwards along GR and HR , so that they meet and concentrate in a point, or rather

Fig. 1.

a line of light parallel to the intersection of the mirrors. Now, the phenomenon, which is thoroughly remarkable, lies on each side of the bright band n . At a short distance, s , there is a dark band; beyond which we find another bright band $n's'$; beyond that again a second dark band $s's'$, and so on in regular alternation to a considerable distance from the central band n . Should one of these mirrors be obscured, all this fringing vanishes; and the entire space is evenly covered by a diffused light;—a striking

$n' \quad s' \quad c' \quad r' \quad n' \quad c' \quad r' \quad A \quad n \quad s \quad c \quad r \quad n \quad c \quad r \quad n$

Fig. 2.

and with edges perfectly defined and clean. An obscure or black band, r , lies on each side of the slit. Beyond this, symmetrically disposed, we find a fine and complete spectrum, n ,—the violet being at n , and the red at c . Another dark interval succeeds; after which we have a succession of spectra, $n's'$, &c.—all, like the first, having the violet nearest the slit; only, the red of the second spectrum overlaps the violet of the third; and so on with the fourth, until the phenomenon fades quite away. Those special dark lines of Fraunhofer (*q.v.*) are found in all spectra of diffraction; but their relative distances are altered. The following appears to be a law;—selecting any distinct line r' , its distance $r''A$ in the second spectrum, from the image of the slit A is double of $r'A$; and $r'''A$ is triple of $r'A$;

III

experimental confirmation of the apparently paradoxical maxim, that *light added to light may produce darkness*. But as this curious fringing resembles, in almost everything, the phenomena attending the edge of the geometrical shadow of an opaque body, and as no hypothesis of molecular attractions and repulsions can explain the experiment of Fresnel, it is clear that such hypotheses must be abandoned in the former case also.—Both these experiments are extremely simple, and may readily be performed by the *Amateur*. One explanatory remark, however, is necessary. To obtain alternate dark and bright fringes, the light concentrated by the lens, must be homogeneous light, i.e. it must consist of rays of one kind only. The ordinary white light of the sun is not simple light, but a sheaf of seven different elementary rays, only one of which—*e.g.* the red ray—must be employed, if the foregoing pure effect is desired. Should the usual, or composite beam be made use of, the results will be found much more complex, although likewise much more brilliant. By the process which originates the fringes, the white beam (*see below*) is decomposed; and instead of alternate dark and light bands, a succession of fine spectra appears on each side of the central band n , in Fresnel's experiment—a similar series fading away from the edge of the shadow, in the other case. Nothing can well exceed the beauty of the appearances frequently evolved by this decomposition. Take, for instance, the case so profoundly analyzed by Fraunhofer. If a ray of ordinary solar light be transmitted through a narrow slit, and examined by a telescope adjusted to distinct vision of the slit, the phenomena indicated by fig. 2, immediately declare themselves. The slit A appears in the middle, of a white light,

&c.—These and all other peculiarities have been fully explained by the general theory whose outlines we shall now endeavour, under a few heads, to unfold.

(1.) *Diffraction; the General Principle on which it Depends.*—The *Undulatory or Wave Theory of Light*, and that special consequence of it—the principle of *Interference*, will be treated at large under several appropriate articles. Nevertheless, the reader must at present have clearly in view the nature of that Theory, as well as of the principle of Interference. According to accepted opinions, Light is not propagated by particles emitted from the luminous body, at extravagant speed; but—as *Sound* is propagated—by waves excited in a highly elastic medium, by the luminiferous body. To use an illustra-

portion of obstacles in the way of the wave, or the cutting off, in various manners, of the action of certain numbers of the points near z , upon points near P . Let us treat the phenomena, by arranging them into classes. — I. Imagine a screen, vz , interposed, so that the whole of one side of the wave xzx' be intercepted by it.

Fig. 4.

It is plain that upon any distant point P' , no effect will thus be produced, because its oscillations must, as we have seen, be determined by the oscillations of the points close to the unaffected part of the wave at z' . Fringes, or whatever else shall be developed by the interposition of the obstacle or screen vz , cannot therefore extend far from P :—but what must be the condition of P' , a point quite near P ? This will be readily understood by aid of our next figure. Suppose xzx' , a small portion of the wave propagated from

that all points of it act in producing the oscillation of P' ; in other words, in illuminating P .

Fig. 5.

Let the total action of one-half of it be called 1; then the whole light received by P , or the total action of both sides of the wave, will be 2. Neglect at present the action of the side xz' : and around P , as a centre, with the radius Pz , describe an arc $z\kappa$. Next take a set of points $B, s, B', s', \&c.$, so placed that $Bz, sT, B'T', s'T'', \&c.$, shall represent the lengths of half an undulation, a whole undulation, an undulation and a-half, two undulations, &c. Two propositions will be accepted at once:—*first*, that zB must be greater than Bs ; Bs greater than sB' ; sB' greater than $B's'$, and so on:—and, *secondly*, that while the action upon P , of the points in every separate arc, $zB, Bs, sB', B's', \&c.$, may

be considered as *according*, the action of the arc zB must be *discordant* with that of the arc Bs ; Bs discordant with the arc sB' ; sB' discordant with $B's'$, &c.;—the arcs next each other will be in *discord*, while alternate arcs, or those separate from each other by an intermediate arc, will be in *accordance*, in so far as their action on P is concerned. More

definitely, if one set of these *according arcs* transmits to P the *crest* of a wave, the other set will, at the same moment, transmit a *trough*.—The total effect on P , or the condition of P with regard to light, must, if the foregoing consideration be correct, evidently depend on the *difference* of the sums of the actions of the two sets of accordant arcs: i.e. one set of actions—let us say, a wave's *crest*, being due to $zB, sB', s'B'', \&c.$, and another set of actions, or a *trough*, to $Bs, B's', B''s'', \&c.$, the actual oscillation of P will depend on the difference of the two: if the difference is 0, P will be at rest: if the former set are more powerful, P will be in *crest*, and if the latter, P will be in *trough*. But since, as we have seen, these arcs are unequal in length—their lengths diminishing as they recede from z —although the sum of $zB, sB', \&c.$, will be greater than zB alone, the entire sum or the amount of both series, must be less than zB alone:—in other words, the action of the entire arc, which we have valued at 1, *must be less than the action of the partial arc zB* . The student will now be prepared to accept the following conclusions — (1.) Should a screen intercept the whole of the semi-undulation xz' , the point P would be acted on, or illuminated by the semi-wave xz' ,—i.e. it would receive the entire light developed as 1.—(2.) If the edge of a screen is pushed inwards as far as B , the point P will receive *light* 1, and the light also from zB , which, as we have seen, is *more than* 1. The entire light falling on P will therefore be *more than* 2; as P will *seem brighter than if the screen did not exist*.—(3.) If the screen is at s , intercepting sX' , the light received by P will be $1 + (zB - Bs)$,—the action of Bs being *negative* or *discordant*; so that although the screen is farther from it than before, the point P will appear *darker*. An effect precisely opposite must follow when the screen is removed to B' :—in short, by gradually withdrawing the screen, by definite intervals or steps, the point P may be endowed alternately with a greater or less amount of light, than it would have if the screen did not exist. But if the screen be supposed immovable, and the point P to change its distance, the results will be equivalent: from which it follows, that beyond the geometrical shadow of any opaque body or screen, there must always be found a series of alternating dark and bright lines or fringes, parallel to the edge of that body;—which fringes are the first and simplest class of the phenomena of diffraction.—It will be observed that the explanation now given proceeds on the supposition, that we are dealing throughout with the same sort of undulations, or that the light diffracted is homogeneous. If the light be not homogeneous, but, let us say, the ordinary sheaf of rays constituting the solar beam, other results must occur. The position of the alternating dark and bright points, with regard to the point P , clearly de-

pending on the length of the undulation, it is manifest that undulations of different lengths will give rise to separate series of dark and bright points, at different distances from r . In other words, the compound solar ray will be decomposed by diffraction; and instead of an alternation of simple dark and bright bands, we shall necessarily have a succession of spectra. This is the feature which bestows on all this class of phenomena so peculiar a brilliancy: its cause having now been indicated, we cannot again refer to it, because of the limits of this article. — II. The next peculiar or critical phenomenon due to diffraction consists in this: *If a narrow opaque body be placed within a cone of rays, issuing from a bright point, a set of fringes will be formed, extending from either side WITHIN the limits of the geometrical or true shadow.* We shall easily reach the cause of this, by aid of the subjoined figure.—Let r , as before, be the bright point or focus of the rays, $r r'$ the opaque screen, $o o'$ the limits of the shadow, and $x r r' x'$ a section or front of the wave proceeding from r ; the question is, what will occur, or what motion will be propagated to r , any point within $o o'$? There cannot be a doubt

that the phenomenon is due to some operation akin to that already analysed; for if one side of the wave $r' x'$ be intercepted by another screen, the dark and white bands, or the fringes, will at once disappear. How then is an interference produced by the action of one side of the wave upon the other side of it, in as far as the point r is concerned?—On each side of the wave, take the points A, B, C, D , and A', B', C', D' , so that the lines $r A, r B, r C, r D$, may differ from each other by half the length of an undulation, and that the same may be the case with $r A', r B', r C', r D'$, &c. Let us now inquire what

Fig. 6

line may represent the direction along which all the motions propagated by the arcs $r A, A B, B C$, &c., might, if compounded, be supposed to act on r . Since the arc $r A$ is greater than the arc $A B$, and since it also lies more directly or less obliquely in regard of r , it is clear that its positive effect will quite overbalance the negative effect of $A B$; so that their combined effect must be positive, or what is the same thing, they must together send a definite quantity of light to r . Similar considerations will show — since, viz.: the other arcs go on diminishing in size and increasing in obliquity—that the resultant of the action of all the arcs taken together must lie along such a line as $r A$ within $r A$, and that the portion of light sent to r , along $r A$, will

depend on the breadth of the screen, its distance from the luminous point, and the position of the point r within the geometrical shadow. Exactly in the same way, the total action of the arc $r' x'$ may be represented by an undulation, transmitted from $r' A'$ along the resultant $r' r'$; so that the condition of r , as to undulation, will depend on the effect, on each other, of the motions transmitted along $r A$ and $r' r'$. (We omit, as too abstruse for this paper, any discussion of the intensity of the vibration transmitted along these resultants.) Thus much understood, the necessity of fringes, or of dark and bright bands, becomes readily apparent. First, at the point r in the axis of the shadow, the lines $r A, r A'$ —which then are $r A, r A'$ —being equal, the transmitted undulation must be in the same phase; i.e. the central band of the shadow must be a bright band. Secondly, as r diverges from r , towards either side, the lines $r A, r A'$ will become more and more unequal; at length a position will be reached by r at which they differ by half an undulation; in other words, the position of a dark band. A dark band therefore will be found on either side of the central bright band. Thirdly, as r diverges still farther, the difference of $r A$ and $r A'$ will further increase, and must soon reach the length of a whole undulation; in other words, next to the aforementioned dark band on either side, a bright band or point must be found: and so on alternately, just as these phenomena actually appear.—It is a sufficiently singular consequence of this peculiar mode of diffraction, that if a small opaque circular disc be placed within a cone of rays, the centre of the shadow of the disc will be illuminated, as if the disc had been transparent.—III. Very remarkable phenomena, due to the same class of causes, occur when a beam of light passes through a narrow aperture, such as $a b$. Our limits oblige us to leave the student, as to the operations in question, simply with the annexed figure; but the deductions already laid before him, furnish an easy clue. It must suffice that we state successively what the results are. The geometrical representation of the aperture on the screen ought, of course, to be bright: but there are fringes exterior to it, or penetrating within the dark space; and interior fringes, or fringes that variegate, and in so far obscure the bright space. (1.) When the aperture is extremely narrow, these exterior fringes are discerned; but as it often happens that,

Fig. 7

in the immediate neighbourhood of the aperture, they get mixed up with the interior system, it is necessary, in order to observe them purely, that the shadow be received on a screen at a considerable distance. Their laws, which are curious, were first deduced from Fresnel's fundamental doctrine, by Biot and Pouillet. (2.) It is sufficiently evident, that in all such cases, interior fringes must be produced; and the theory is beautifully verified by an experiment—the reverse of the one alluded to in the previous section—viz.: that a beam of light passing through a narrow circular aperture, shows a dark spot in the centre of its projection on a screen.—In the cases now mentioned, as in others already alluded to, the purity of the results depends on the homogeneity of the light employed. In all other circumstances, coloured fringes and even spectra, often of great brilliancy, are produced.—IV. Many interesting questions connected with diffraction have not been touched in this article; for instance, the inquiry as to the hyperbolic paths of these fringes in space, or as traced backwards from the edge of the opaque body; and still farther, the case of interference by reflection, or those phenomena of colour produced by striae on polished surfaces, as which the discoveries and researches of Sir David Brewster have bestowed so fresh and peculiar an interest.—The space that remains to us must be occupied by a brief reference to a few of those brilliant results so carefully studied by Fraunhofer—the effects of diffraction when the ray passes through a delicate *net-work*. Taking the simplest case of a system of narrow openings, such as below, it is clear that various

Fig. 2

sets of openings may be made out of it; for instance, two parallel sets crossed, will form an extremely delicate set of square holes, &c., &c. If the parallel system be employed, and the light which has passed through

Fig. 2

is decided by that series of magnificent

spectra of diffraction already described (page 174). If, by crossing two parallel systems, a set of square holes is produced, the spectator beholds a circular figure, of which the preceding diagram is a quadrant (fig. 9), in which the white rectangular figures are spectra, more or less elongated, but exceeding brilliant. If, again, a set of small round apertures, close on each other, be employed, the subjoined still more remarkable appearance bursts on one's sight—

Fig. 10.

each oval space being, as before, a complete and dazzling spectrum. But experiments of this sort may be infinitely varied; and they never fail to bring new pleasures to the inquirer.—We refer the student further to articles on *this* and *thick plates*,—see PLATES.

(3.) *Diffraction; Exemplified in Natural Phenomena.*—Certain practical and natural results of diffraction are too important to be passed without notice.—1. Several curious appearances in the foci of telescopes are attributable to this cause. (1.) If the telescopic image of a fixed star is examined by a magnifying power exceeding 200, we discern first a circular disc with perfectly clean circumference; and secondly, around this disc a system of dark and bright rings, with slightly coloured edges. Diminish the opening of the object-glass, by a diaphragm in front of it, and the image of the star augments until it assumes the aspect of a planet—the rings enlarging at the same time, and becoming more distinctly coloured, manifesting well pronounced shades of white, red, black, and blue. Arago observed, further, that if the eye-piece be gradually pushed in, the disc darkens at its centre, becoming at last quite black: as the eye-piece is pushed farther inwards, the black centre enlarges; then a luminous point appears at its centre; and this bright point, enlarging in its turn, comes to manifest a central dark point, which also goes through similar changes. Also, if the eye-piece is fixed for a short time at a position showing an image with a dark centre, and if this image be closely inspected, a brilliant point will ever and anon burst out within the obscure disc, and then suddenly disappear. This latter phenomenon, however, occurs only in the case of *scintillating stars*. See SCINTILLATION.—(2.) Sir John Herschel has, by ingeni-

ous experiments, added considerably to our knowledge of this curious subject: he placed diaphragms of *various shapes* in front of the object-glass, and obtained thereby the following curious results. *First*, with a diaphragm or opening shaped as an equilateral triangle, the annexed figure gives the image the star: i.e. the

Fig. 11.

disc of the star surrounded by a dark ring, and six straight rays, thin, but sufficiently brilliant. Three of these rays point to the angles of the triangular diaphragm; three to the middles of its sides. If the eye-piece be slightly pushed in, the figure changes into this:—

Fig. 12.

Secondly, an aperture formed by the interval between two concentric squares, gives the subjoined curious appearance:—

Fig. 13.

And, *thirdly*, from an assemblage of small equilateral triangles regularly arranged, an image

Fig. 14.

like that of fig. 14 is observed,—an image com-

posed of a series of circular discs, arranged along six symmetrical and equal rays, which unfold the brilliant colours of the spectrum.—The whole of these curious phenomena, and many others like them, issue from interference,—the rays being diffracted by the edges of the diaphragm.—II. A very large class of the phenomena of optical meteorology, are referable to *Diffracti*on:—we shall specify only *Crowns* or *Coronas*, and *Anthelia*; phenomena already described under the proper articles.—These coronas or *concentric coloured circles*, surrounding the sun and moon, present, in regard of their colouring, the characteristic of all phenomena of diffraction, viz.: the *exterior* part of the spectrum is *red*; the *interior*, *violet*. The diameters of the several circles increase, as the numbers 1, 2, 3, 4, &c.,—a law discerned, as necessary, by Young, and recently confirmed, by delicate observation, by M. Delezenne, of Lille. The doctrine of *interference* easily explains this law. The production of *coronas* may be illustrated experimentally in the following easy way. Cover a piece of glass with dust of *lycopodium*, and look through it at the sun, the moon, or even the flame of a candle,—superb *coronas* will immediately appear. Now, this is the exact process in nature:—natural coronas being formed whenever we look at these luminaries through a great number of small spheres or globules of water, of a uniform or nearly uniform diameter,—globules placed between us and the sun by the agency of a peculiar cloud. The apparently paradoxical optical principle which these globules bring into operation, will now be readily understood: it is simply this; if, slightly beyond the line joining the eye and a luminous point, a small opaque body be placed, its effect will be precisely the same, as that of a similar opening illumined by the incident light; so that whatever the degree of the body's apparent opacity, in that same degree it produces an actual illumination. This indubitable and fertile principle readily explains a singular phenomenon described by Necker of Geneva. If the sun rises behind a hill covered with trees or brushwood, a spectator in the shadow of the hill, and *quite near the line* of the solar rays, sees all the small branches projected on the sky, not opaque or black, but, on the contrary, white, silvery, and brilliant, as if the vegetation were really composed of silver. The same theory of Interference also explains the aspect of those globules floating in the air, when a ray of the sun penetrates a dark room; likewise the colouring of spider's threads, or thin metallic wires, &c. *Coronas* really exist around the sun much more frequently than one imagines; but they cannot be seen in general because of the dazzling light of that orb. They are most easily found on looking at the image of the sun in a mirror blackened on one side. Every transparent cloud, except the *cirrus* and *cirro-stratus*, produces them; and the fogs form-

ing in the valleys over night, and rising towards mid-day to the tops of mountains, yield appearances of this kind of admirable brilliancy. — *Anthelia*, as already described, are colours seen around the shadow of one's head, &c., when that shadow falls on a cloud, on the grass, a field of corn, or any other surface covered with dew, &c. Bouguer first observed this among the Cordilleras. Lamartine, on the summit of Lebanon, saw his head surrounded by a superb glory: the same thing has been seen elsewhere. While *Coronas* are produced by the agency of transmitted light, *Anthelia* are due to *reflected*, or to a *retrograde transmission*. But the theory is the same: it is easy to pass from the phenomena of transmission to those of reflection or retrograde illumination. The same formulæ of interference apply in both cases.

Diffraction, Dynamical Theory of. The leading phenomena of *diffraction*, as connected with the general idea of the undulatory theory, are explained above. But many other, and much more difficult problems, start up on a full consideration of this curious subject. For instance, that fundamental one,—in what manner, according to what mathematical and dynamical laws, is each wave of a series broken up as it passes the edge of a diffracting body, or falls upon a small aperture? How shall we represent the exact condition of the secondary waves issuing out of it, and thus come to a complete understanding of all the details of the illumination in front of that aperture? The inquiry has been pursued in all its generality, in a remarkable and very pregnant memoir by Professor Stokes, published in the ninth volume of the *Transactions of the Cambridge Philosophical Society*,—a memoir containing, besides, exceedingly interesting contributions to general dynamics. It is not within reach of this cyclopædia to do more than make reference to such memoir; but there is one part of Mr. Stokes' investigation, bearing so closely on an important question in reference to the general theory of light, and so interesting at the present moment, that it seems incumbent to treat it in some detail.—The student who has at all looked into modern speculations regarding light, does not require to be reminded that the vibrations of the molecules of a light wave are supposed to take place *transversely* to the length of the wave, or to its *advancing course*: they are not like waves of sound, but like the vibrations of a musical string when in tension. In the same manner, in the case of a ray of *common* or *unpolarized* ray of light, these vibrations take place at the same time in *all transverse* directions—just as when a string is moved from its repose, not by one pull only, but by a great number of pulls in all directions. In the case, on the other hand, of what is called a *plane-polarized* ray, these vibrations take place in one transverse direction only—as when a taut string is made to vibrate by

being pulled aside in one direction only. The vibration of the molecules in a plane-polarized ray must thus be all parallel to some one fixed transverse line; and the question that remains is, to what line are they parallel? Are they parallel to the plane of polarization itself, or perpendicular to it? Now this is no mere curious question, but, on the other hand, closely connected with our notions of the habitudes of the light-ether under different circumstances. But the most eminent physicists differ in their conclusions—Fresnel and Cauchy holding ultimately by the theory of perpendicular vibrations, while MacCullagh maintained the opposite hypothesis; nor was any effort made to discover an *experimentum crucis*, previous to these researches on diffraction by Mr. Stokes. His method was simple. Suppose that a plane-polarized ray reaches a grating in a direction perpendicular to the plane of the grating, it is not difficult to discover the plane of polarization of the diffracted ray; and the plane of polarization of the incident ray is of course also known. Now the following theorem holds,—if the angles between the plane of polarization of the diffracted rays and the lines of the grating be less than the angle between the same lines and the plane of polarization of the incident ray, then the vibrations must be *parallel* to the plane of polarization; if the contrary obtains, the vibrations must be *perpendicular* to that plane. Mr. Stokes performed the experiment by aid of a fine glass grating, on which parallel lines were ruled of 1,800 to the inch; and the issue seemed decisive in favour of the latter hypothesis, or Fresnel's. But doubts so grave have since then supervened, that the important question must still be considered unsettled. One of the most experienced physicists, M. Holzmänn, resumed the inquiry in 1856, on the ground of Mr. Stokes' theory—performing the experiment, also, with a slight modification. He did not use a grating made by diamond lines on glass—to which he objects, as having irregular edges—but one of Schwerdt's lamp-black gratings; and he maintains, as a determinate result, that the *vibration of light occurs in the plane of polarization*. It is the earliest wish of all physicists that Mr. Stokes should find leisure for resumption of the investigation. If the two conclusions are incapable of being harmonized, at least we may expect to discover the causes of their conflict. Nor can the unsettled state of such a question be regarded otherwise than as a serious blot on the undulatory theory, as it at present stands.

Diffusion of Light and of Heat; Diffusive Power. On analyzing what is termed the *reflecting* power of bodies, with regard to Light, it is found that a very important distinction requires to be made. A total or pure reflection of *light*, for instance, from the surface of any body, would convey to the onlooker no conception whatever, either of the size or colour

of the reflecting substance; the only result would be, a perfect presentation of the source of the incident beam,—its direction from the eye being all that would be altered by the reflection. But by all mirrors—even the most perfectly polished, more is done than that;—the eye which notices the reflexion, notices also the *form* of the mirror, and in some degree its *colour* also. Besides the pure geometrical reflexion, therefore, the incident beam undergoes other two distinct operations. *First*, there is an *irregular reflexion* in all directions, from the inequalities of the surface of the mirror, dispersing incident light on every side, and revealing the mirror's form; and *secondly*, there is a *diffusive power* which disperses also in all directions a portion of the incident light *after having altered it*, or after having impressed upon it that *special colouring* depending on the nature of the body. In article COLOURS, reference has been made to the difficulties connected with this question of the natural colours of bodies: it is sufficient, therefore, to give here a simple definition of the term *diffusion of light*.—Now, what occurs with regard to LIGHT, happens also with reference to HEAT: but certainly the difficulty of determining exactly how much of the efficacy which is not absorbed is dispersed by irregular reflexion, and how much by such *diffusion*, is not diminished in the latter case. The endeavour to reach such a determination has occupied the well known Melloni. It is quite established, for instance, that a white matted surface reflects much more (or *absorbs* much less) than a blacked surface: but the question is, in what manner is the light reflected sent away? Melloni conceives that there is at once a large irregular reflexion, and a peculiarity in the amount of that irregular reflexion depending on the nature of the incident ray of heat—in other words, a true *diffusive power*:—it requires, perhaps, to confirm his idea, that the nature of the dispersed rays be minutely examined, so that it be determined whether they correspond in nature with the incident rays, or have acquired new properties?—Melloni further speaks of a supposed diffusion of heat by transmission, that is, when the rays emerge through an unpolished surface, when they are issuing from a *diathermanous* or *thermanizing* substance. It does not appear, however, that the rays issuing in this way from a *rough* surface of rock salt or glass differ from the rays issuing from polished surfaces of these substances: i.e., those issuing from a polished surface of rock salt have all the characters of the source from which they emanated, while those issuing from glass are merely *thermanized*, as they ought to be: no change, therefore, is impressed on them by the rough surface, except *change of direction*: but the astonishing fact is, that a rough face of rock salt blacked by smoke, *does not impress on the emergent rays any deviation whatever in point of*

direction.—The student is especially referred to a remarkable memoir by Knoblauch, in Taylor's *Scientific Memoirs*. See also RADIANT HEAT; RADIATION.

Diffusion of Liquids, Gases, &c. A term applied to a curious phenomenon, discovered first by Priestley, brought again under notice by Dalton, and of recent years very fully investigated by Dr. Thomas Graham. It is virtually this:—let volumes of two liquids or two gases, having no chemical relationship whatsoever, be brought into contact with each other (if only by a narrow connecting tube) there will immediately ensue a flow or translation of the two into each other, until the two separate volumes become interfused,—the distribution or quantities of the two separate elements depending on their respective specific gravities. The student is especially referred to Graham's remarkable Memoirs in the *Transactions of the Royal Society of London*, republished in the *Philosophical Magazine* during a few years prior to 1851.—As to *Liquids*, Adolf Fick of Zurich has recently made an interesting attempt to develop a fundamental law. (*Pogg. Annalen*, vol. cxciv). Proceeding on the supposition that the law for the diffusion of a salt in its solvent must be identical with that according to which the diffusion of heat in a conducting body takes place—the law on which Fourier founded his celebrated Theory of Heat, and which Ohm applied in determining the diffusion of electricity in a conductor—he finds that the transfer of salt and water occurring in a unit of time between two elements of the same salt, must, *ceteris paribus*, “be directly proportional to the difference of concentration and inversely proportional to the distance of the elements from one another.” Fick carries out his fundamental idea by aid of ingenious mathematical processes, which promise to co-ordinate at least the larger number of Graham's facts.—In reference to *Gases*, Graham conceives that the ratio of dispersion depends on the specific gravity of the gas—the lightest travelling fastest—the rate of diffusion being exactly as the square root of the density of the gas. Inquiries as to this point were instituted some years ago by Bunsen in conjunction with Professor Stegmann. The former has more recently resumed the subject, employing an apparatus and manipulation alike novel and ingenious. He thinks he has established that the pores of the gypsum diaphragms generally used to separate the gases in experiments, do not, as usually supposed, act as fine openings in thin plates, or as gratings, but as a system of capillary tubes: and he negatives the opinion formerly received, “that the volumes of two diffused gases, when interfused, are inversely as the square roots of their densities.” The inquiry, however, is confessedly in an unfinished state. The student is referred to Bunsen's *Gasometry*, translated by Mr. Roscoe.

DIG

Digester (Papin's). An instrument originally employed to extract, as far as possible, the nutritious matter from bones. It is not for this, however, that we mention it here. It consists of a strong iron vessel in which water may be boiled, and the lid of which is so fixed down as to be nearly as capable of resisting force from within as the rest of the vessel is. Heat being applied after the vessel is filled, steam is formed as usual. When water boils in ordinary circumstances, the pressure of steam never rises above 14.7 lbs. per square inch (the atmospheric pressure), nor the temperature of either the water or steam above 212° Fah. In the digester, if the lid be so constructed as to open under a little less than would burst the vessel—say 5 lbs. of extra pressure per square inch—we may raise the temperature of the water and the temperature and pressure of the steam very considerably higher. The principle of all high pressure engines is illustrated by Papin's digester. See SAFETY VALVE.

Dilatation. Increase of bulk. See EXPANSION.

Diophantine Analysis. That section of the theory of unlimited problems, which attempts to find rational and commensurable values answering to certain equations between squares and cubes. Thus, it is properly a problem in the diophantine analysis, to find all the values of x and y , constituting $x^2 + y^2$ an exact square. We shall subjoin methods of solution for one or two of these unlimited or indeterminate problems, in the way of example. No general rules of treatment are, or can be, laid down:—Let $5x + 7y = 29$, it is required to find corresponding integral values for x and y .

Since $5x + 7y = 29$

$$x + y + \frac{2y}{5} = 5 + \frac{4}{5}$$

$$x = 5 - y + \frac{4 - 2y}{5}$$

Now, in order that this may be a whole number, it is evidently requisite that the fractional

part $\frac{4 - 2y}{5}$ shall be a whole number. Let then

$$\frac{4 - 2y}{5} = n.$$

$$\therefore 4 - 2y = 5n$$

$$2 - y = 2n + \frac{n}{2}$$

$$2 - 2n - \frac{n}{2} = y$$

That this may be a whole number, it is necessary only that n shall be even. Hence, in order that y shall be an integral number, and x also, it is

necessary that $y = 2 - 2n - \frac{n}{2}$ and $x = 5 - y$

$+ \frac{4 - 2y}{5}$ where n may be any even number.

The values so found for x and y will satisfy the

DIO

original equation.—Thus let $n = 2$, then $y = 2 - 4 - 1 = -3$ and $x = 5 + 3 + 2 = 10$, and $5 + 10 - 7 \times 3 = 29$. Again, let $n = 0$, then $y = 2$, and $x = 5 - 2 = 3$, and $5 \times 3 + 7 \times 2 = 29$.—Next, let it be required to find a number, such that if divided by 3, 4, and 5, successively, the remainders will be 2, 3, and 4, respectively. Suppose that number, x .

Then $\frac{x}{3} = p + \frac{2}{3}$, where p is a whole number,

$$\text{and } x = 3p + 2$$

Also $\frac{x}{4} = q + \frac{3}{4}$, where q is a whole number,

$$\text{or } \frac{3p + 2}{4} = q + \frac{3}{4}$$

$$3p - 1 = 4q$$

$$p = q + \frac{q + 1}{3}$$

And if $\frac{q + 1}{3}$ be a whole number, p will be so.

Let $\frac{q + 1}{3} = r$, then $q = 3r - 1$ and $p = 4r - 1$.

Hence $x = 12r - 1$, where r is a whole number.

Also $\frac{x}{5} = t + \frac{4}{5}$, where t is a whole number.

$$\frac{12r - 1}{5} = t + \frac{4}{5}$$

$$12r - 1 = 5t + 4$$

$$2r - 1 + \frac{2r}{5} = t$$

If therefore $\frac{2r}{5}$ be a whole number, t will be a

whole number, and tracing back the process, x will be a whole number, and divisible by 3, 4, and 5, with remainders 2, 3, and 4, respectively.

This will take place when r is any multiple of 5: e.g. let $r = 5$, then $x = 12 \times 5 - 1 = 59$, which number answers the conditions. Let $r =$

10, $x = 119$, another number also so answering, and so on.—*Thirdly*, let it be required to find two

square numbers whose sum shall be a square, e.g., to find two numbers whose square roots

might represent the legs of a right angled triangle, in which the hypotenuse is commensurable

to the legs.—Let x^2 and y^2 be the numbers. Then $x^2 + y^2 = z^2$. Let us suppose $z = x -$

ny , a quantity which may be made anything we please by adjusting the value of n .

$$x^2 + y^2 = x^2 - 2nxy + n^2y^2$$

$$\therefore y = -2nx + n^2y$$

$$y(n^2 - 1) = 2nx$$

$$y = \frac{2nx}{n^2 - 1}$$

Given any value of x , then, y will be found by substitution in this formula, so that x^2 and y^2

shall be an exact square. Suppose that we wish to get x and y integers also as well as z ,

then $\frac{2nx}{n^2 - 1}$ must be an integer, as it evidently

will be if $x = n^2 - 1$ and n be an integer. In that case y will be $= 2n$ and $x = n^2 - 1$, there being no limitation regarding n but that it shall be an integer.

Let $n = 1$, then $y = 2$, $x = 0$, and $2 = 2$.

Let $n = 2$, then $y = 4$, $x = 3$, and $2 = 5$.

Let $n = 3$, then $y = 6$, $x = 8$, and $2 = 10$.

And so on.

On this Diophantine analysis—so called from its discoverer Diophantus—has been reared the extensive subject of the Theory of Numbers by Legendre and Gauss.

Dioptrics. The two changes of fundamental importance, in Geometrical Optics, occur when a ray passes from a medium by which it is readily transmitted on to a medium by which it is not transmitted but thrown back; and when it passes from one transmitting medium into another, different in kind from the first, as, for example, from air into water. Geometrical Optics treats of the first, under the name of Catoptrics (or Katoptrics), (see CATOPTRICS,) and of the second, under the name Dioptrics. The subject of Dioptrics, therefore, is the transmission of rays of light from one medium into another, differing in kind. The laws, upon which the whole of Dioptrics rests, are the following:—When a ray of light passes from void space into any medium, it is bent from the straight line; but it proceeds onward in the plane which contains the perpendicular to the boundary of the medium at the point of its entrance, and the line of its original course. Thus, when a ray passes from void space, through a spherical piece of glass, if we draw a line perpendicular to the glass through the point where the ray strikes, and imagine a plane to pass through this perpendicular and the ray, the light will pass through the glass somewhere along that plane. The second law is this:—The sine of the angle which the ray makes with the perpendicular already described, bears a definite ratio, differing for every kind of medium, to the sine of the angle which the transmitted ray makes with the same perpendicular, produced. In other words, if SP be a ray falling upon a glass XPY , and PS' the direction of it while passing through the glass, and if QPQ' be perpendicular to the surface at P , then, when we take any point such as B , and a corresponding one like B' , equi-distant with it from P , and draw BA , $B'A'$ at right angles to QAQ' , BA and $A'B'$ will bear, the one to the other, a certain ratio, which can be experimentally determined for each medium. Certain definitions enable us to state these two laws in shorter space. The *Angle of incidence* of a ray, is the angle contained between any given ray and the perpendicular to the bounding surface of

Fig. 1

the medium into which it passes, at the point where it falls upon it. Thus QPS is the angle of incidence of the ray SP , and RPQ of the ray RP . The *Angle of refraction* is the angle made by the direction of the transmitted ray—as it passes through the new medium—with the perpendicular line produced. Thus $Q'PS'$ and $Q'PR'$ are the angles of refraction in the two cases respectively. The *angle of deviation* is the difference between the angles of incidence and refraction. Thus, the line SP being produced to Z , the angle ZPS' is the angle of deviation. The dioptrical laws can now be stated thus:—1. The incident and refracted rays are in the same plane with a perpendicular to the surface limiting the medium entered. 2. The sines of the angles of incidence and refraction bear a certain ratio, constant in the passage of any ray from vacuum into any given medium, at whatever angle the limiting surface is met by the incident ray. These laws hold absolutely with regard to homogeneous light. As to the latter law, however, the ratio of which we have spoken, differs for different kinds of light. Hence, if a refracting substance, such as a triangular prism, of very finely ground and very transparent glass be presented to a ray, so that it may freely pass through it, the different colours will be separated one from the other, and the ray

the medium into which it passes, at the point where it falls upon it. Thus QPS is the angle of incidence of the ray SP , and RPQ of the ray RP . The *Angle of refraction* is the angle made by the direction of the transmitted ray—as it passes through the new medium—with the perpendicular line produced. Thus $Q'PS'$ and $Q'PR'$ are the angles of refraction in the two cases respectively. The *angle of deviation* is the difference between the angles of incidence and refraction. Thus, the line SP being produced to Z , the angle ZPS' is the angle of deviation. The dioptrical laws can now be stated thus:—1. The incident and refracted rays are in the same plane with a perpendicular to the surface limiting the medium entered. 2. The sines of the angles of incidence and refraction bear a certain ratio, constant in the passage of any ray from vacuum into any given medium, at whatever angle the limiting surface is met by the incident ray. These laws hold absolutely with regard to homogeneous light. As to the latter law, however, the ratio of which we have spoken, differs for different kinds of light. Hence, if a refracting substance, such as a triangular prism, of very finely ground and very transparent glass be presented to a ray, so that it may freely pass through it, the different colours will be separated one from the other, and the ray

Fig. 2

will be thrown along the space RF , presenting in detail an appearance like that below. The lines re-

Fig. 3

will be thrown along the space RF , presenting in detail an appearance like that below. The lines re-

Fig. 4

present spaces which appear dark in the spectrum, and the spaces marked red, orange, &c., are spaces where rays of those colours predominate. In order to give an idea of the differences in refraction to which the different rays are subject, we transcribe the subjoined table from Herschel's Treatise on Light. The numbers are the values of what is called the refractive index (the value of the fraction, $\frac{\text{sine of angle of incidence}}{\text{sine of angle of refraction}}$, or (in fig. 1)

$\frac{BA}{B'A'}$) for the different dark lines of the spectrum.

There are many more of these lines, but those marked by the capital letters have their position and refractive indices best known.

The full consideration of this refractive power as varying in the different coloured rays, belongs to physical optics. We shall, in this place, consider rays, as composed of perfectly homogeneous light (i.e., light possessing the same refractive properties, and having the same refractive index). The first consequence from these two laws is this: When a ray is incident upon a refracting substance, of which the two surfaces (at which it enters, and from which it emerges) are plane and parallel, the course of the ray after emergence is exactly parallel to its course before incidence. We shall give a somewhat circuitous proof of this, for the sake of avoiding the use of trigonometry. Let

Fig. 5.

SP be an incident ray, refracted along the line PR, and emergent at P', from the substance, of which ABCD is a perpendicular section, and in which AB and CD are parallel lines, along the line P'Q, then P'Q is parallel to PR. Draw the perpendiculars ER, E'F, upon AB and CD, and make PR, P'F, each equal to P'P'. Draw ER, and P'F parallel to AB and CD. Produce SP to Q. It is necessary to premise that the law of refraction is utterly indifferent to the direction of the ray of light, and that it holds equally

when a ray passes from vacuum into a medium, or from a medium into vacuum. If one ray enters a medium from void space, and if another ray of the same kind of light passes through the medium in a line coinciding with that of the refracted ray, it will emerge into vacuum, and pass through vacuum along the original course of the first ray. According to the laws of refraction, the line PR will bear a certain proportion to R'P', and the line P'F will bear the same proportion to EP, the side of the rectangle opposite to R'P', and therefore equal to it. PR and P'F will then be equal. We have now two right-angled triangles, PRF, and P'F'E', in which PR and P'F, being each equal to P'P', are themselves equal, and the sides RF, E'F' have been shown to be equal.—We have, therefore, SPQ and P'S' parallel.—The next consequence of importance is, that if a number of parallel rays fall upon a plane surface, the lines of direction of the refracted rays are also parallel; a conclusion we shall not stop to demonstrate.—It may have been noticed, that in the figures hitherto given, the refracted ray is bent inward. This invariably happens when a ray passes from vacuum into any medium, and the contrary happens when it passes from any medium into space. In the first case, the ray is bent towards the perpendicular which passes through the medium; and in the other, is bent from the perpendicular which passes through vacuum. The table already given illustrates this. The following table shows how this fact is expressed, in accordance with the refractive law; and at the same time may give an idea of the different refracting powers of different substances. The refraction is calculated for rays of mean refrangibility

DIO

—those between the violet and the red rays of the spectrum.

The meaning of the table is this:—in passing from vacuum to common air, the ratio of the sines is 1.000294; that is, if sP be the course through vacuum, and $s'P$ through common air, then $s'A' = 1.000294$. The ratio of sA to $s'A'$ in the case of a passage from vacuum to any substance is given opposite its name. Two general results follow readily from the table;—*first*, the refractive index is greater in passing into denser, than into rarer media; and *second*, the same index is greater also in passing into the more combustible media.—Up to this point, we have proceeded on the idea, that the ray of light passes from vacuum into another medium, or from another medium into vacuum. But in the great majority of instances, the ray passes from one medium into another. This case, however, is met by the laws already noticed. Given the absolute refractive indices of two media (the index for the passage from vacuum into each of them), it is easy to find their relative refractive index (that for the passage from the one into the other). The relative index in passing from one medium into another, is the quotient of the absolute index of the second by the absolute index of the first. When the ray passes through one medium into a denser one, the relative refractive index will be measured by the quotient of one quantity (the refractive index of the denser) divided by another less than it (the refractive index of the rarer), and will therefore be greater than 1. The ray will thus be bent towards the perpendicular to the bounding surface. And the reverse must hold when the ray proceeds in the

DIO

opposite direction.—It is worth noticing, that the refractive index of common air is very small, and that when we take the relative refractive index for air and a medium, very little alteration is required in the original absolute index of the medium; unless indeed, for the gases, whose indices, being likewise small, are very sensibly altered, in consequence. Thus the relative refractive index of a mean ray passing from air to glass is 1.4985, when that for such a ray, passing from vacuum to the same glass is 1.5.—Another very important proposition is this, that if we have a series of media, all of which are separated at their boundaries by parallel surfaces, any ray passes through one of the series, just as if it had entered it from vacuum. Thus, if we imagine, in fig. 6, two originally par-

Fig. 6.

allel rays $sPQRS'$ and $A'B'B'A'$, coming both from vacuum, and passing through the medium $BQRB'$, the rays will be transmitted through the medium in parallel lines.—This is a very direct and easily deducible consequence. The lines $s'R$ and $A'B'$ are parallel; so also, the lines $B'B$, and RQ . But the latter has passed through a medium before entering $BQRB'$ and the former has not.—It is important to notice a limitation requisite in the application of this statement, to the ordinary refraction of stellar and solar light in passing through the atmosphere. The

Fig. 7.

atmosphere is imagined to be, and for the purposes

of calculation we consider it generally as composed of a series of layers of equal density passing all round the earth, those of each density being at equal elevation. Let x represent the position of a spectator at the surface and ace, bdf , two adjacent atmospherical layers. oz is directed towards the zenith. Let $xa, ba, xc, ds, es'', xs, fs''$ be luminous rays. Then the surfaces bdf and ace are curved surfaces, and therefore it is impossible to describe them as parallel. If, however, a plane be drawn just exactly touching a curved surface at any point, it is said to have the same direction with the surface at that point. Now, in refraction, we have only to do with a point of the limiting surface. It is clear that it would not, in the least, signify, although we should have, instead of the straight line rq , a hollow line z , in the vertical section

Fig. 8.

of the body. It is equally clear, that it does not matter how near r or q , such a hollow line may come, if it only leave room for sr to fall on exactly the same spot as it would otherwise do, and do not interfere afterwards with the directions sr . Hence, in refraction, we have only to do with a very small part of the bounding surface, and that the part at which a ray is incident or emergent. We can substitute, therefore, instead of the surfaces ace, bdf , three planes just touching them at a, c and e , and at b, d , and f . The condition of which we have spoken, that the uniting surfaces be parallel, in order to the application of the propositions demonstrated, will be fulfilled, therefore, if the plane which touches the outer circle at b be parallel to that touching the inner at a . This again will happen, if the lines ag and bh are parallel. For any planes are parallel, the perpendiculars to which are parallel lines. Now these straight lines ag, bh, ck, dl, em, fn are all continuations of the radii through a, b, c, d, e, f . These lines ag, bh, ck, dl, em, fn , when brought to one point at O , are readily seen not to be parallel, and therefore the planes of which we have already spoken are not to be considered so either. Hence the law which we have demonstrated, for parallel boundaries cannot be applied to atmospheric refraction. It is useful to observe, however, that in the case of rays passing down as far as from s near the zenith, the deviation from the case which we have already considered is very small. The triangle EOa is

very much elongated, and the angle EOa , by which the directions of the perpendiculars and therefore of the planes differ, is very small. Taking a radius of two degrees or so, round the zenith line, we may cut out a conical portion of the sky, like $p\pi b$, differing very little from a real cone, and having the luminous lines passing through A to R , passing into the layers of different densities very nearly at parallel surfaces. In fact, for this space, the deviation from the law stated could not well be estimated. In this case, then, in computing the exact amount of refraction, we simply take the original ray as coming to the eye, in a line, the refractive index for the deviation of which from the original line is 1.000,294, subject to certain minute corrections for temperature and pressure. This is liable to no material error, for the refractive index for air has been very frequently observed. In the case of rays nearer the horizon, we have different and far less simple laws, akin to those for prismatic refraction; and the correct application of these is dependent upon our knowledge of the physical constitution of the atmosphere; and is disturbed by any temporary disarrangement of that constitution, for example, by winds, earthquakes, meteors, &c.—We shall now proceed to consider the case most analogous to atmospheric refraction through the strata nearest the earth's surface. It is that of refraction through a prism. The general character of a prism, as we now consider it, is simply a body not bounded by parallel surfaces. When a transmitted ray strikes, at its points of incidence and emergence, on planes which are not parallel, or upon surfaces, the tangent planes to which at these points are not parallel, our previous conclusions do not hold, but become useless. We must consider this case specially. Conceive two planes, standing out at right angles to the plane of the paper, and making on that plane the figure BAC . Let sr be a ray of light from a luminous point, s , falling on the plane at P , and following the course sr, q, r . The problem requires the discovery of the laws which regulate the transmission of the ray (supposed of homogeneous light) sr, q, r .

Fig. 9.

The first proposition we shall establish is this,—the algebraic sum of the angle of refraction at the first surface, and the angle of incidence at the second, is equal to the angle BAC , contained between the two planes. Draw mn' and $n'n$ perpendicular to the sides. Then $n'PQ$ and $n'QP$ are respectively the angles of refraction at the first surface and of incidence at the second. It is asserted that their algebraic sum is equal to EAP . The angles $n'QA$ and $n'PA$ are each right angles. The whole four angles $n'QA, n'PA, QAP, Qn'P$ make up four right angles

DIO

(I. 32 cor.) It follows, therefore, that $Q N' P$ and $Q A P$ will make up two right angles. Again (I. 82) $Q N' P$ and $Q P N'$ with $N' Q P$ make up also two right angles. The addition of $Q A P$, therefore, and of $Q P N'$ with $N' Q P$ to the same quantity $Q N' P$, gives the same result, and $N' Q P$ and $N' P Q$ must be equal to $Q A P$. We may imagine the line $Q P$ becoming nearer and nearer to $Q N'$, until, in some cases, it comes to coincide with it, as in the figure, where $P Q$ and the line $Q N'$ are the same. In that case the angle $P Q N'$ has vanished, and the proposition just proved, if true, would require that $N' P Q$ should itself be equal to A . But as this is a limiting case, we cannot trust our conclusion without verifying it. Thus, therefore, $Q P N'$ and $Q P A$ make up the right angle $N' P A$, and $Q P A$ and $P A Q$ are equal to the right angle $B Q P$. It follows as before, that $Q A P$ and $N' P Q$ are equal. The proposition is, therefore, true in this case also. We have imagined that the line $Q P$ crept up towards $Q N'$ as the position of the ray $S P$ changed. Might it not be conceived to have passed it and got to the other side? It is evident that it might, assuming the position of the figure below. But

Fig. 10.

in this new case the result is the same. It follows from the above, that the deviation of a ray, caused by such passage through planes, is always towards the thicker and from the narrower part of the prism, if it be denser than the surrounding media, and in the opposite direction, if rarer.—We shall proceed to find expressions for the amount of deviation, in terms of the angle of the prism and of the relative refractive indices of $A B C$ and the surrounding media. Let δ = angle of deviation (EDR , fig. 9, EPR , fig. 10, PDR , fig. 11). Let i be the angle of incidence at

Fig. 11.

the first surface, i' that of refraction; e the angle of emergence from the second surface, e' that of incidence upon it, and α that of the two planes represented in section by AB and AC . Thus in fig. 9: $\delta = DPQ + DQP$.

$$= (DPN' - N'PQ) + (N'QD - N'QP) \\ = (i - i') + (e - e').$$

DIO

$$\delta = i + e - (i' + e') \\ = i + e - \alpha,$$

because α , the angle made by the planes, is equal to the algebraic sum of the angles of incidence at the second and of refraction at the first surface. The same proof would show that the statement holds in all the three cases, e becoming $-e$, when the direction of RQ changes with respect to mQ' , as in fig. 11. Then

$$\sin i = \mu \sin i',$$

$$\text{and } \sin e = \mu' \sin e',$$

where μ and μ' are the relative refractive indices for a mean ray passing from the two surrounding media into ABC . Take for the sake of simplicity, *e.g.* the more usual case—media on the two sides of the same kind (μ and μ' being equal). The more general investigation proceeds on the principles which we are about to apply, but demands the introduction of higher mathematics.

$$\therefore \sin i = \mu \sin i'$$

$$\sin e = \mu' \sin e'$$

$$\alpha = i' + e'$$

In these three equations, we have got three unknown quantities defined, i' , e , and e' , and it would be possible by the application of not very recondite geometrical principles, to get these expressed in terms of the various known quantities, i , μ , μ' and α . We must confine ourselves still further, however,—viz.: to three special cases, capable of resolution without difficulty. Suppose i to be very small. But the sines of very small angles are nearly proportional to the angles themselves. Hence we may substitute for the expressions $\sin i$ and $\sin e$, &c., i and e , &c. And we obtain

$$i = \mu i'$$

$$e = \mu e'$$

$$\alpha = i' + e'$$

$$\delta = i + e - \alpha = \mu i' + \mu e' - \alpha = \mu (i' + e') - \alpha \\ = \mu \alpha - \alpha = (\mu - 1) \alpha$$

Applying this formula, to the case of a prism of glass, with an angle of 60° , we will have

$$\delta = (\mu - 1) 60^\circ \\ = (1.5 - 1) 60^\circ \\ = .5 \times 60^\circ = 30^\circ$$

—The second special case we shall consider, is that in which the angles of incidence and emergence are equal. Taking our standard formulæ —

$$\sin i = \mu \sin i'$$

$$\sin e = \mu \sin e'$$

$$\alpha = i' + e'$$

We shall then have $i = e$; whence, from the first two formulæ $i' = e'$. (This merely asserts a proposition already established, viz.:—that two parallel rays are refracted parallel, in the same circumstances.) Instead of having the rays parallel, conceive that the sides BA and BC after having been together, are carried away separate. Since i and e were equal when they were together, the rays were parallel then, and the angles of refraction were therefore equal then. But if the system—the glass and the ray—be merely removed, with no change in their relative

DIO

positions, the refraction must remain quite as before.

$$\text{Hence } i' = \frac{a}{2}$$

$$\text{Now } \delta = i + e - a = 2i - a$$

$$\text{But } \sin i = \mu \sin \frac{a}{2}$$

$$\therefore i \text{ is the angle whose sine is } \mu \sin \frac{a}{2}$$

$$\text{And } \delta = 2 \times (\text{angle whose sine is } \mu \sin \frac{a}{2}) - a.$$

—Our third special case, is more general than any of the others. It does not assume that the media, on the two sides, should be the same: in fact, it takes in the most general application of the case conceivable, when the ray emerges perpendicularly. In that case $e = 0^\circ$; whence e' is also equal to 0° .

Hence, taking our formulæ—

$$\begin{aligned} \sin i &= \mu \sin i' \\ \sin e &= \mu' \sin e' \\ a &= i' + e' \end{aligned}$$

We have $a = i'$

$$\sin i = \mu \sin i' = \mu \sin a$$

$$\therefore i = \text{angle whose sine is } \mu \sin a$$

$$\text{and } \delta = i + e - a = i - a = (\text{angle whose sine is } \mu \sin a) - a$$

Applying these two last formulæ to the case of a glass prism of 60° at A, (taking μ , the relative refractive index of air and glass, as 1.5), we have, when the angles of incidence and emergence are equal, (in this case, by the way, the deviation is proved, by the higher mathematics to be the least possible)

$$\begin{aligned} \delta &= 2 \times \text{angle whose sine is } .75 - 60^\circ \\ &= 2 \times 48^\circ 35' - 60^\circ = 87^\circ 10' \end{aligned}$$

and when the ray emerges perpendicularly to the bounding surface, which might, in this case, be placed in water, (the other boundary surface being kept above it),—we have $\delta = \text{angle whose sine is } 1.299037 - 60^\circ$. A most anomalous result, for no angle has a sign greater than 1. The inference is, that it is impossible to transmit a ray through a prism with a refracting angle, so that the emergent ray be perpendicular to the surface of emersion. This result is sufficiently interesting; but it becomes more so, when it is viewed as an inevitable consequence of the refractive law; and when another class of analogous results, depending on the same principle, are brought up to confirm it. The refractive index from a rarer to a denser medium is always greater than 1. Suppose it μ . But in every case of refraction, the formula $\sin i = \mu \sin i'$ applies.

If now $\sin i'$ be greater than $\frac{1}{\mu}$ (and whatever μ

be, since $\frac{1}{\mu}$ must be less than 1, some angle may be found whose sine would be so), we should have $\mu \sin i'$ greater than 1; but $\mu \sin i'$

DIO

is equal to $\sin i$, and $\sin i$ is therefore greater than 1, which is impossible. Either, therefore, the refractive law is incorrect, or some false hypothesis has been made. That hypothesis is, that light could be refracted into a medium at an angle of refraction whose sine is greater than $\frac{1}{\mu}$, or, which is the same

thing, that if passing through such a medium, any ray could in these circumstances, be refracted out. We arrive, therefore, at the conclusion, that light is not refracted into a medium at an angle of refraction whose sine is greater than $\frac{1}{\mu}$. For example, all light, passing

into water, will be refracted at angles of refraction whose sines shall not be greater than

$\frac{1}{1.331}$ (1.331 being the least refractive index, for the red ray, through water, and the rays so refracted will be red; violet rays will not be refracted at an angle whose sine shall be greater than $\frac{1}{1.844}$. (See table 1, already given.) The

red rays, therefore, may fall within $48^\circ 42'$ (angle whose sine is $\frac{1}{1.331}$), and the violet rays

within $48^\circ 4'$ (angle whose sine is $\frac{1}{1.844}$), of

the perpendicular to the surface at the point at which they enter. The $38'$ between the two would be very beautifully tinged with the prismatic colours. Hence to an eye below water all the objects at the surface of the earth will appear as if grouped into the space of $97^\circ 24'$, instead of appearing, as they do, at the surface under an angular space of nearly 180° . The eyes of fishes have very nearly the same density and refractive index with the water in which they live; there is, therefore, no material change in this effect to them.—We have thus obtained, then, by the above processes, expressions for δ in terms of μ and a . It remains to deduce similar expressions for μ in the terms δ and a . Sometimes we have peculiar specimens of refracting substances, whose exact power we wish to discover, and in order to this we measure δ for a prism with a given refracting angle. The expressions which we shall deduce refer respectively to the three cases already specified.

In the first case we found $\delta = (\mu - 1) a$

$$\frac{\delta}{a} = \mu - 1$$

$$\frac{\delta + a}{a} = \mu$$

Thus, in a prism of 60° refractive angle, if δ be found to be 38° , we obtain $\mu = 1.55$; from which, it is probable that the glass is a low flint glass, containing lead in composition. (*Herschel on Light.*)—In the second case

DIO

$$\delta = 2i - a, \text{ and } i' = \frac{a}{2}$$

$$\mu = \frac{\sin i}{\sin i'} = \frac{\sin(\frac{\delta + a}{2})}{\sin \frac{a}{2}}$$

Take similarly $\delta = 30^\circ$

$$\text{Then, } \mu = \frac{\sin 45^\circ}{\sin 30^\circ} = 1.414$$

In the third case,

$$\delta = i - a$$

$$i' = a$$

$$\therefore \frac{\sin i}{\sin i'} = \mu = \frac{\sin(\delta + a)}{\sin a}$$

Let $\delta = 30^\circ$, here also

$$\mu = \frac{2}{\sqrt{3}} = \frac{2\sqrt{3}}{3} = 1.151.$$

—The subject of the refraction of light at the surfaces of various curves, and of the convergence and divergence in the refracted rays, will be fully treated under article LENS. Another subject, closely connected with dioptrics, and depending upon dioptrical principles, is the appearance which bodies make to the eye behind refracting surfaces. This will be treated of elsewhere. See LENS and TELESCOPE. We shall just state the propositions upon which it rests. Its principle is very simple. Every line or surface, luminous either in itself or by reflection, is supposed to be made up of a number of luminous points placed closely together. The rays from these appear, after passage through the prism, as if they came from points entirely different from those from which they are really emitted, according to the laws already demonstrated in this article. For each point, therefore, we will get another corresponding point, from which the rays, really emergent from the first, will apparently emerge. The whole of these corresponding points, put together, will make up a line or a surface, as the original body made up the one or the other, and the problem which we now just indicate is this—Given a line or a surface made up of luminous points, required to find its position, as that appears through a refracting body? This may be the case while the eye remains in one medium and the body in another, only one of which terminates between the body and the eye. A fish seen in water is such a body. Or again the body and the eye may be separated by a medium completely terminating between them, as a stick seen through glass. We have shown in this latter case, that the point from which the rays will seem to an eye on the other side of the medium, to emerge, will be at

the distance $u + \frac{t}{\mu}$ from the surface of the medium—approximately. If, therefore, we have an object *given*, and draw from its points various perpendiculars to the farther surface of the

DIP

plane medium of which we speak, and mark off, from the points of incidence of these perpendiculars, distances equal to $u + \frac{t}{\mu}$ respectively, (μ being the relative refractive index, and u the perpendicular distance of each point of the object from the plane surface), we shall obtain the image required. It would be easy to show, for example, that the image of a straight line so obtained will also be a straight line, parallel to the first. If, as in the other case, the medium be not terminated between the object and the eye, we should have $u' = \mu u$ as the formula to be applied for each point, where u' is the distance of the point from which the rays appear to emerge, from the bounding surface, and u the distance of the point from which they actually come. In this case also, the image of a straight line would be a straight line. It is to be noted carefully, however, whether the eye is situated in the denser or in the rarer medium. As this changes, μ and $\frac{1}{\mu}$ change places. Thus, also the relative refractive index of water and glass is μ , when that of glass and water is $\frac{1}{\mu}$. In the case of the fishes seen in water, the value of μ is less than 1, because equal to the reciprocal of a number greater than 1, and fishes will therefore always appear nearer the surface to an eye above it, than they really are. The refractive indices for various kinds of water vary, but that given in the second table, 1.336 may be taken as the standard value. The distance, then, of a fish from the surface of still water will be 1.336 times more than the apparent distance. In the case of the virtual images (images occupying the points from which the actual light appears to proceed) formed by prisms, the principles are more complex. We shall take only one case—that of a prism with a small refracting angle. Suppose that the rays by which the image is really formed are all perpendicular to the two prismatic surfaces. It is then easy to calculate the apparent position of the object. Imagine now the rays from that image falling on the second surface, untouched by the first, and calculate the position of the new image by the same law. This position may be taken as sufficiently near for practical purposes to the real position of the image.—The foregoing paper, referring only to the leading phenomena of Dioptrics, does not pretend to exhaust the subject. The advanced student is earnestly referred to a recent memoir by Gauss, reprinted in *Taylor's Scientific Memoirs*.

Dip of Horizon, is the angle which the line drawn from the eye to the most distant visible object on the earth's surface makes with the rational horizon. It is impossible to observe the dip on the surface of the ground, because of its inequalities. It is readily observed, however,

DIS

at sea. The dip of the horizon is affected by refraction. See REFRACTION. As far as it is not so influenced we shall explain it here.—A spectator situated at E , above the surface of the earth, will see any object above the lines EA , EB . He cannot see below these lines. The angle then which either of these lowest lines makes with FEH , which is drawn perpendicular to EC (C being the centre of the earth), and which is so, parallel to the horizon of D , the point immediately beneath E , on the surface, is called the dip of the horizon. Thus, in the figure, either $\angle EBF$ or $\angle EBH$, is so.—It is easy

to calculate its amount. The angle FEA is equal to $\angle ECA$, and when we know ED , it is not difficult to find the value of $\angle ECA$. If we add ED to the length of the radius of the earth at the spot, and divide that same length of the radius, by the sum, we obtain a decimal, which will be found in trigonometrical tables of cosines, opposite the angle we seek.—If, as is more frequently the case, we wish to know the length of space EA , over which we can range at a given height, we may obtain a very near approximation by multiplying ED by four times the diameter of the earth, and extracting the square root. This will give the diameter of the circle of vision. It is to be noted, however, that the approximation is the less accurate the larger ED becomes, and that if it exceed a mile or two we must employ other expedients.—It is necessary to remember that results thus obtained, must be corrected for refraction.

Disc. (*Discus, a quovis.*) An astronomical term signifying the part of the surface of a heavenly body visible at any given time. Disc is also employed in optics, although rarely, to signify the width of aperture of telescope glasses.

Discharge. In the article upon Conduction of Electricity we described the several modes of electric discharge, or of the transference and annihilation of the electric forces. One of these modes, the disruptive discharge, will be specially considered in this article, as it is that to which the simple term Discharge is most usually appropriated. If an electrified conductor is insulated and brought near to another conductor, it electrifies the latter by induction, and has its own charge determined with greater or less intensity towards that part of its surface which lies nearest to the induced charge. Up to certain limits, the intensity of this electric action may be increased by several means, as by bringing the surfaces nearer to each other, by increasing the charge upon the conductor, or by

DIS

changing the forms of the surfaces: but the increase, however effected, has a limit in every case. In this limiting state of the inductive actions, a spark appears between the surfaces, accompanied by sound and other effects, and the electric forces are found to be wholly or partially destroyed. In other words, discharge has occurred *across the air*; and it is called the disruptive discharge because of the sudden and violent commotion that it produces in the matter occupying its path. The conductors may be separated by other substances as well as air, for the production of these effects. Discharge between their surfaces may be effected across any kind of interjacent matter, gaseous, liquid, or solid, which possesses a certain degree of insulating power. When the interjacent matter is solid, it is shattered, or cracked, or pierced, by the disruptive action, so as to be permanently unfitted, by its loss of insulating power, for the repetition of discharge through its mass. On this account, solid media of discharge cannot be employed to any great extent in the investigation of the laws of this electric action. The laws of discharge in air have been investigated with much attention and success by Sir W. Snow Harris. A full account of his methods and results is given in the *Philosophical Transactions* for 1834. The principal subject of his inquiry was, the quantity of electricity requisite for the production of discharge in given circumstances: and of his valuable results we may mention two, which are remarkably simple and definite, and which have been verified under such varied forms of experiment, as to be well entitled to the name of general laws. If two electrified conducting balls are made to approach one another in air, they discharge, to each other, across the air, when their mutual distance has diminished to a certain value. This amount is called the *striking distance*. In constant circumstances, the striking distance is constant. It varies with several elements; particularly, with the forms and magnitudes of the conducting surfaces, with the amount of their charges, and with the condition of the surrounding air. In the two laws above mentioned, the striking distance is related mathematically to the amount of the charges and to the density of the air. For the same balls, the striking distance varies exactly in the direct ratio of the charge, and in the inverse ratio of the density of the air. Thus, let one ball be connected with the ground, and let the other be charged by the unit jar with one, two, or three units of electricity; then the striking distances between the two balls across the air will be in the three cases as one, two, and three. Again, if the two balls be enclosed in an air pump, and the air be rarified, the striking distance for a constant charge increases, and precisely in the same proportion as the density of the air diminishes; and in these circumstances a constant striking distance is maintained by diminishing the charge

in the same proportion as the density. Faraday has made numerous experiments upon disruptive discharge, as may be seen in the twelfth series of his *Experimental Researches*. One inquiry of great interest which he has attempted in those experiments is, the dependence of the striking distance upon the specific nature of the gaseous medium interposed between the conductors. It had been commonly supposed that the power of air and gases in restraining discharge, up to the limiting intensity of inductive action, was due to statical pressure upon the conducting surfaces. This view, however unsatisfactory, was not without support in fact, as may be seen from the second law above stated. But Faraday's results have rendered it more than questionable, by proving the existence of specific restraining powers in the several gases. Thus, the striking distance in muriatic acid gas is about one-half of that in common air in similar circumstances, and barely one-third of that in hydrogen. The restraining power of muriatic acid is therefore three times that of hydrogen. This is for the same pressures; and similar differences, though not so extensive, are observed among the other gases. These differences cannot be attributed to specific gravity, for the orders of the gases in respect to these two properties are not the same. The differences are founded, according to all appearance, upon specific electric distinctions among the gases in relation to discharge. This fact appears the more remarkable, when we consider that all the gases have sensibly the same inductive capacity: but a similar contrast has long been established in the case of air at different densities. Faraday's experiments on disruptive discharge appear to have brought out another specific difference among the gases. When two charged balls of different dimensions are brought near to each other in air, the discharge is restrained more powerfully when the *smaller* ball is that positively electrified,—other things being equal. A similar law holds in *hydrogen*, *olefiant gas*, *carbonic acid*, and *muriatic acid*; while the reverse appears to hold in *oxygen*, *nitrogen*, and *coal gas*. Some of these results are still questionable; but a *specific difference* in this respect, has been certainly established. For full information upon these points the reader is referred to Faraday's *Experimental Researches*, series twelfth and thirteenth; where the bearing of the facts upon the theory of electricity is also brought out pretty fully. We should not omit reference to the variety of forms assumed by disruptive discharge in the gases. These are described by Faraday under the names of spark, brush, glow, and dark discharge. The first three of these are sufficiently indicated by their names, to all who have witnessed the common optical effects produced by electric machines in action. Their theoretical connection is simple enough; for the brush has been actually analyzed into a quick succession of spark-discharges, and

the glow may be supposed to consist of discharges in still closer succession. The dark discharge, as far as it has been yet observed, occurs in connection with the glow. When two balls, for example, discharge to each other through rarified air, there is exhibited, in certain circumstances, a perfectly dark interval in the space between the balls, and this while the whole space appears to be traversed by the discharge. It is even considered probable that there are dark discharges analogous to the spark and brush, but not luminous in any part. In the old theory, the phenomena of discharge in air, were explained as the result of the mutual attractions of the electricities, opposing and overcoming the resistance of the air. The latter resistance was generally identified with the statical pressure of the air upon the conductor. This theory was a natural interpretation of the more elementary facts; but it is now giving place to the theoretical views of Faraday. One of the great excellences of the latter theory is the strictness of connection that is established among the varied phenomena of electricity, a strictness so well sustained even in the present undeveloped state of the theory, that it is difficult to give separate explanations of electric phenomena without tedious reference to other phenomena. Induction, according to Faraday, is the result of a forced mechanical condition of the particles of a dielectric. When a body is placed between two electrified conductors, its particles are thrown into this forced condition, by the electric forces resident upon the conducting surfaces. The intensity of this condition is exalted by the approximation of the conductors, until the particles *throw off* their forces, by communication to each other; and this constitutes discharge in general. Disruptive discharge differs from conduction according to this theory, not in kind but in degree; the limiting intensity of the forced inductive condition of the particles being very great in the former case, and very small in the latter.

Dispersion of Light. It is shown, under REFRACTION, that the *sine* of the angle of the rays *incident*, upon a refracting medium, is proportional to the *sine* of the angle of *Refraction*; in other words, that the ratio

$$\frac{\sin i}{\sin r}$$

is constant for the same medium. This ratio is termed the *index of refraction* for that medium. But as it is well known that the ray of light consists of parts, or is a *sheaf of rays*, unequally refrangible, and that on this account it becomes, after refraction, the coloured *spectrum*—it is clear that the angle of refraction above spoken of, is merely the *mean angle*. Each colour, indeed, has its own *index of refraction* for every separate medium or refracting body; nor have we been hitherto enabled to trace the physical connection between the indices

DIV

of refraction of the different colours, and other qualities of the refracting substance—one colour appearing contracted, and another remarkably developed, when the ray is subjected to the refringent action of different media. The dispersion of light, strictly speaking, is the difference of the refracting indices of the two extreme colours—red and violet—of the spectrum produced by any substance: and—(the ratio of its dispersion, to its mean index of refraction diminished by unity)—what is called the dispersive power of that refringent substance, is measured by means of that. But, as every one who has seen a spectrum knows, the various

DIV

colours are spread indefinitely over a considerable space,—so indefinitely that it is not possible to state accurately, either the beginning, the end, or the middle of any colour. The exact measurement of dispersion would thus have been impossible, but for the remarkable discovery, by Fraunhofer, of the dark bands. The character of these is fully explained under FRAUNHOFER'S LINES, as well as the circumstances under which they may be readily discerned. The actual spectrum, as seen through a telescope, would be represented correctly, if the upper portion of the accompanying figure, or R' U', were superposed on its under or coloured part. These

dark bands belong to the different colours over which they are placed in this figure, and whatever the refringent or dispersive medium, they retain their place in relation to these colours. Instead, therefore, of having to deal with an indefinite coloured space, we can deal with a definite dark line belonging to that colour; and Fraunhofer, as well as all subsequent inquirers, have adopted for this purpose, the lines B, C, D, E, F, G, H. By aid of these rays, the indices of refraction of the different colours, in reference to all refracting media, may be formed and tabulated; and the dispersive power of such media computed. Such observed and computed tables are given at length in all good writers on optics. It suffices here to have stated their origin and nature.—Nor can we omit to remark, that such determinations are essential to the scientific completion of ACHROMATISM.

Dispersion Epipollic or Superficial; Dispersion Internal; Fluorescence. Terms variously applied to a class of phenomena of which the explanation has recently been given by Professor Stokes in several memoirs, that constitute an epoch in the history of our knowledge of the affections of light. Indications of the existence of an action on light, not known before, by substances of various kinds, had not escaped the notice of Sir David Brewster and Sir John Herschel. Sir David clearly pointed out that he had noticed these as early as 1838; and Sir John Herschel entered more fully on the subject in 1845. What attracted Herschel was as follows:—Solution of quinine, which, when viewed by transmitted light, is colourless as water, does yet in certain aspects, and under certain incidences of that light, exhibit a celestial blue colour. This colour, according to Herschel, comes only from a stratum of fluid, of small but finite thickness, adjacent to the surface at which the light enters. Brewster asserts that he has seen the light considerably farther from the surfaces; and

he identifies it with a property belonging to fluor spar—(hence naming it *fluorescence*). He refers it to a common, or rather an extensive class of facts, included under the name of “internal dispersion.” The light thus transmitted is found capable of being dispersed by the prism, and to consist of rays of various refrangibilities—none of them, however, belonging to the red end of the spectrum. Herschel could discern no traces of polarization, on examining it by the tourmaline; Brewster, on the other hand, on using a rhomb of calcareous spar, conceives that he certainly detected traces of this condition. The investigations of this latter eminent inquirer will be found in the *Transactions of the Royal Society of Edinburgh* in 1846, and again in the *Philosophical Magazine* for June, 1848.—Matters remained in this state until the year 1856, when Mr. Stokes took up the problem. Struck by the fact, that while the rays that enter the fluid cannot pass through, or affect more than a trifling thickness of the fluid, the dispersed rays themselves traverse many inches of that fluid with perfect freedom, he felt himself shut up to the conclusion, that the rays producing dispersion are in some way of a different nature from the rays dispersed. Now, in what quality or qualities can two sets of light-rays differ from each other? Under the modern theory of light, a ray is distinguished or individualized by two circumstances—its period of vibration and its state of polarization; or, as we may rather say, its degree of refrangibility and its state of polarization. Pursuing the latter hypothesis in reference to its power to account for the phenomenon now before him, Mr. Stokes shows it to be utterly untenable, and thereby found himself driven to suppose that the difference of nature between these two sets of rays is a change of refrangibility. But from the time of Newton it had been believed that light retains its refrangibility through all the modifications which it may undergo. “Nevertheless,” says

Mr. Stokes, "it seemed to me less improbable that the refrangibility should have changed, than that the undulatory theory should have been found at fault. And when I reflected on the extreme simplicity of the whole explanation, if only this one supposition be admitted, I could not help feeling a strong expectation that it would turn out to be true. In fact, we have only to suppose that the invisible rays beyond the extreme violet give rise by internal dispersion to others which fall within those limits of refrangibility between which the retina of the human eye is affected, and the explanation is obvious. The narrowness of the blue band, observed by Sir John Herschel, would merely indicate that the fluid, though highly transparent with regard to the visible rays, was nearly opaque with regard to the invisible. According to the law of continuity, the passage from almost perfect transparency to a high degree of opacity, would not take place abruptly; and thus rays of intermediate refrangibilities might produce the blue gleam noticed by Sir John Herschel, or the blue cylinder, or rather cone, observed by Sir David Brewster. We should thus, too, have an immediate explanation of a remarkable circumstance connected with the blue band, namely, that it can hardly be seen by strong candle-light, though readily seen by even weak day-light. For candle-light, as is well known, is deficient in the chemical rays situated beyond the extreme violet."—That a ray of Light should be definitely changed in its refrangibility, by its passage through a medium, was indeed a new truth in science; and it opens a boundless sphere of investigation as to the relations of the Ethereal Medium with the molecular constitution of the bodies that so influence its vibrations. Nothing in modern times has been substantiated which is so fertile, and so sure to evolve, ultimately, momentous results. Various inquirers, and some speculative thinkers, *e. g.*, the Abbé Moigno, in his fundamental objection to some conclusions by Sir David Brewster—(see *SPECTRUM*) have imagined the possibility of such a change; but the honour of having established it, belongs to Mr. Stokes.—We add one of the most general of the conclusions of his first Memoir.

"The phenomena of internal dispersion oppose fresh difficulties to the supposition of a difference of nature in luminous, chemical, and phosphorogenic rays, but are perfectly conformable to the supposition that the production of light, of chemical changes, and of phosphoric excitement, are merely different effects of the same cause. The phosphorogenic rays of an electric spark, which, as is already known, are intercepted by glass, appear to be nothing more than invisible rays of excessively high refrangibility, which there is no reason for supposing to be of a different nature from rays of light."

Divergence: Divergent Series. Lines which constantly recede, one from the other, are

termed *divergent*. For instance, two adjacent radii of a circle *diverge*.—A *divergent series*, in Algebra, is an infinite series of this sort:—if, on stopping at any term of it, and taking the series as there terminated for the whole series, we cannot say that the error committed lies within a definite amount or limit,—that series is a *diverging* or *divergent series*.

Diving Bell. See BELL, DIVING.

Divisibility. All ordinary bodies are supposed to be made up of a considerable number of parts, which may be separated one from another. Every body, however small, must have a certain volume; and as this *volume* can be divided in abstraction infinitely, we may imagine an infinite number of lines drawn on the surface of the body, or through it, marking the boundaries of its different cohering particles. If these particles be not joined by an infinite force, there must be some finite force capable of separating them. If, therefore, we cannot conceive an infinite force, we are driven to believe in the infinite divisibility of matter; and such a force we cannot conceive.—But although we are led to a belief in the infinite divisibility of matter, it by no means follows, that we can divide it infinitely. The smaller atoms may be held together by forces perfectly sufficient to resist the most powerful that we are able to apply. The metaphysical question admits of metaphysical argument; but no actual result is ever likely to throw light upon it.—Passing from it, therefore, we next ask, do we ever find in practice a limit higher than the mere imperfection of the senses, and therefore of instruments constructed for, and adapted to, them, where the division of matter stops? The answer is clear and decisive—we do not. Our progress in dividing bodies seems only limited by the imperfection of our senses and of our implements.—Thus, in the case of liquids and gases, there must be evidently a very great divisibility—for water is easily separable from water at any point, and yet the most powerful microscope is unable to detect interstices. No inequalities can be perceived upon their surface, either by the eye or the touch.—All experiments, in fact, tend to show, that the divisibility of matter is almost, if not altogether, infinite. A fibre of silk has a thickness of $\frac{1}{8000}$ th of an inch, a fibre of merino is about twice this in the thickness of its diameter, and the fibres of the ordinary hair in animals, with the finer furs, are between these. Yet each of these very thin fibres contains a complete system—with parts distinct in nature and in properties—which we do not find to adhere powerfully, where we can test that adherence.—A tube of glass presented to the blowpipe, and drawn very carefully out will come to be as fine as this silk fibre, while retaining its character as a tube, with a distinct exterior and interior surface. The polish which metals take, is another striking instance of their divisibility. It is produced

by rubbing them with hard grains, which make an indefinite number of little holes at the surface, instead of a smooth surface. But these are so minute, that the same touch by which a fibre of silk is easily felt, cannot detect them. Particles, therefore, as small, or smaller than would fill these holes, have been detached from the mass. When a soap bubble is blown, and not allowed to detach itself, just before it bursts there is a place at the top where a black spot appears—the rest of the bubble displaying all the colours of the rainbow. This is $\frac{1}{1000000}$ th of an inch in thickness. We can blow glass so thin, that this same phenomenon will be visible; and then the glass must be of this same thickness. Divisibility is strikingly illustrated by the thinness of wires. Wollaston placed a platinum wire, $\frac{1}{100}$ th of an inch in diameter, in the centre of a silver wire $\frac{1}{4}$ th of an inch. He then drew them through a drawing plate, and the result was that, as the platinum constantly maintained its proportion to the silver; when the latter was $\frac{1}{1000}$ th of an inch, the former was $\frac{1}{10000}$ th in diameter. The silver was then dissolved away by nitric acid, which left the platinum wire. Divisibility is well illustrated by the case of odours. A room, the supply of air in which is regularly renewed, will be perfumed for months by a little musk exposed in it; while yet no loss can be detected in the weight of the musk. This odour is caused by the floating in the air of odoriferous particles dispersed through it. The most striking instances of divisibility are found in the animal and vegetable kingdoms. Wherever we find two bodies, differing in nature, in juxtaposition, we conceive that the mass made up of the two is divisible. Proceeding upon this principle, let us consider a drop of blood. This has been discovered microscopically to be made up of a very great number of globules, differing in size and form, according to the species. In man, and in the other mammalia, for instance, they are spherical; and in birds and fishes, elongated. In man, again, they are $\frac{1}{1000}$ th of an inch in diameter; in the goat, in which they are smallest, about $\frac{1}{1500}$ th of an inch, and they vary between this and $\frac{1}{1000}$ th of an inch. Now in all these globules there is a distinct chemical constitution; all of them are made up from distinct parts of the body, and therefore all of them are minutely subdivisible.—Finally, there are animals as small as these globules of blood. We cannot prove that they have organs. But we find them move, and this requires a complicated organism. They are capable of directing themselves to the accomplishment of ends—of shunning obstacles—and even of vanquishing them. All these properties, microscopically discovered, prove the existence within them of a complicated organism, and therefore the smallest object which we can perceive must be yet indefinitely divisible. Great and little, in truth, seem in

creation alike terms expressing merely relation to us, and vanish in the universe of the Infinite God.

Division, in *Arithmetic*, an operation the reverse of multiplication. Its symbols are $b \) \ a \ (: \ \frac{a}{b} : \text{ or } a \div b.$

Division, in *Astronomical Instruments*, signifies that graduation of their arcs or circles, by which equal parts—the measures of equal angles—are marked out on them. The practical art of *division* is now carried to very high perfection. The late Troughton greatly advanced it by his exquisite dividing engine; and continental artists have certainly not lagged in the race. In this country, astronomical circles are usually divided primarily into every five minutes of arc: on the continent they carry primary subdivisions farther—as far as two minutes of arc. These primary intervals are of course again subdivided, in either case, by aid of *Verniers* or *Reading Microscopes* (q.v.) Notwithstanding the extreme accuracy of the mechanical divisions, however, the observer never trusts absolutely to that accuracy. The errors of its division, are among the errors which he conceives inseparable from his instrument; and he does not delay to investigate their amount,—employing the results of his inquiries in accordance with the *theory of corrections*. The investigation is a tedious one, and will be found explained in special treatises on astronomical instruments.

Dome. The spheroidal or spherical top of a building. It is very frequently placed above a circular tower. The *dome*, as distinguished from the *cupola*, signifies the exterior surface; while the *cupola* signifies the interior. The principles of the dome are very much those of the bridge and the arch (see ARCH), and are fully explained in ordinary architectural works.—See VAULT.

Dominical Letter. It is often convenient in historical research to know upon what day of the week a particular event may have taken place, when its date (e.g. 19th January, 1568) is specified. For the purpose of determining this, tables of *dominical letters* are constructed. Their meaning and method of employment is as follows. The seven first letters, A, B, C, D, E, F, G, are connected with the first, second, third, &c. days of every year, A being again connected with the eighth, B with the ninth, &c., A with the fifteenth, B with the sixteenth, C with the seventeenth, and so on. The dominical letter is that letter which falls, according to this arrangement, to the first Sunday (*Lord's day*—*dominus*—*dominical*) of each year. In leap year there is no letter connected with the twenty-ninth of February, but one is missed over for that day. It is evident that the same result will be obtained by taking the letter next to the dominical letter of the year (e.g. E for D) as the dominical letter after that date. Every leap year has two domi-

nical letters, one for the first two months and one for the last ten. If then we have the dominical letter for each year, and tables are constructed, according to the old style and to the new style, which give this immediately, we turn to another table wherein we have the year divided into 52 weeks, thus—

Same day of week for each line.

Jan. 1, 8, 15, 22, 29, Feb. 5, 12, 19, 26, Mar. 5.
Jan. 2, 9, 16, 23, 30, Feb. 6, 13, 20, 27, Mar. 6.
Jan. 3, 10, 17, 24, 31, Feb. 7, 14, 21, 28, Mar. 7.
Jan. 4, 11, 18, 25, Feb. 1, 8, 15, 22, Mar. 1, 8,
and so on.

Then if our first table gives the dominical letter C, the letter corresponding to the third day of the year—the first Sunday of that year is on January 8d. All the days along the horizontal line commencing with it are Sundays also; and according as the commencing days of the other seven lines (Jan. 1st, Friday; Jan. 2d, Saturday; Jan. 4th, Monday; Jan. 5th, Tuesday; Jan. 6th, Wednesday; Jan. 7th, Thursday) are Mondays, Tuesdays, &c., so are all the dates marked along these lines. Should the year be a leap year, instead of C for the dominical letter we shall have C and D; the first, until the end of February; after which, the second, till the end of the year. It is evident that E would be the letter for next year, F for the next, G for the next, and for the fourth A, B. For in each successive year there are just 52 weeks with one day (two in leap year) remaining over, wherefore the letter is put forward. In our usual tables the dominical letter is printed in capitals, and the other letters—corresponding to the other commencing days—in small characters. The dominical letter was introduced by the primitive Christians in place of the *Nundinal* letters of the Roman calendar.

Double Stars. See STARS.

Draco (the Dragon.) One of the old constellations. Its principal stars lie between Ursa Minor, Cepheus, Cygnus, and Hercules. The star, γ Draconis, of the second magnitude, is celebrated as the one used by Bradley in the discovery of aberration. γ and β Draconis are nearly in the line joining Deneb and Arcturus. The extreme star, λ Draconis, between the third and fourth magnitude, is situate very nearly between the pole star and its two pointers. The star, γ Draconis, was so used by Bradley, because it was the largest star passing near his zenith, and therefore fitted to secure at once distinctness of observation, and freedom from refraction.

Ductility is that property of bodies, in virtue of which they may be drawn out in length, while their diameter is diminished, without any fracture or separation of their parts. This property is peculiarly noticeable, and important in the case of the metals. The degree of ductility in bodies is affected—increased or diminished through the agency of heat. Metals are ductile, generally speaking, at any temperature. The

degree of ductility appears always, however, in their case, to be influenced by temperature. Some metals, such as brass, and a kind of iron, called red short, are more ductile at ordinary temperatures than when hot. The only general rule which we can apply is, that the heat at which a body is ductile, is less than that at which it is fusible. While the body remains ductile, there is a force joining the particles together, but when it has become fused, all force has ceased to constrain the junction of particles. Ductility is produced in certain masses, as certain clays, by their intermixture with water: when they are in the medium state between solidity and fluidity, these bodies are ductile. They form, then, a pretty thick paste. The order of the ductility of the metals is very nearly the following, beginning at the highest:—Gold, silver, platinum, iron, copper, zinc, tin, lead, nickel, palladium, cadmium. This is nearly the same order as that of their malleability. There is, therefore, some connection between the two properties, but the relation does not hold universally. Iron, for instance, is extremely ductile, but not very malleable. The connection and the difference, are usually explained thus: That in ductile bodies the particles are interwoven, or rather, consist of short fibres, placed side by side, while in malleable, they form little plates, the one kind sliding by their flat surfaces, the other from extremity to extremity. We shall give one or two examples of ductility. When gold is treated by the gold-beater, Reaumur found that a grain of it could be beaten into a plate containing about 86 square inches. So far, it is malleable without difficulty. It is next spread round an ingot of silver, about an inch and a-half in diameter, and then passed repeatedly through the draw-plate, until the thickness of the thread of silver is not above 1-9000th part of the thickness of the ingot. All this time, the gold remains on the silver, and is spread over the surface, without leaving a single spot uncovered, even when viewed microscopically. The grain of gold is therefore spread over a square of 15 ft. in the side. By pressing even this very thin wire between large cylinders, it is very considerably extended. It is to be noted, however, that if beaten violently with a hammer for some minutes, it will become comparatively brittle; and it is then impossible to extend it much farther. The ductility of glass at a red heat is very remarkable. Threads of the greatest fineness can be made of it. If, for instance, we take a piece of glass, and heat it over a furnace, we may catch some of the heated mass with an iron hook, and draw it away, still adhering to the glass. Lay it now on a wheel, and turn this rapidly, when a number of coils of very fine glass thread will encircle it. The form of these threads is elliptical, one diameter being three or four times greater than the other. Their flexibility is almost as great as that of the spider's web fibres (which is, by the way, itself an

excellent instance of ductility), and it has been even thought possible that articles of apparel might be manufactured from glass fibres, in consequence of their flexibility increasing with the thickness.

Dynamometer. A beautiful little instrument, constructed for the purpose of determining with the greatest possible precision the effective magnifying power of a telescope. It is well known (see TELESCOPE,) that this can be obtained by dividing the focal distance of the object-glass by the focal distance of the eye-piece. Now, if we look through the eye-glass at the image of the object-glass, formed at the common focus, the diameter of the image will bear the same ratio to the diameter of the object-glass, as the focal distance of the eye-glass does to that of the object-glass. If, therefore, we divide the diameter of the object-glass, by that of the image so formed, we shall have the magnifying power. Now, the effective diameter of the object-glass, is one of the data of any telescope, and readily measured. If, then, we can obtain an instrument capable of measuring its image, we shall obtain the magnifying power of that telescope. Such an instrument is the dynamometer. The simplest method, and the one which most readily occurs, is to place a slip of mother of pearl, carefully graduated in, say, hundredths of an inch, near the common focus, adjusting it carefully for distinct vision, and reading off the number of divisions between the top and bottom of the luminous image. This construction does not, however, secure a very rigorous determination of the magnifying power desired. Ramsden was the inventor of the double-image dynamometer, and Dollond improved his construction. Fig. 1 represents the instrument in a side view, and fig. 2 represents a section of it, through the box A B C D. The graduated circle F, is attached to the screw-head E, and turns with it. The screw M and the screw I both enter the nut, but are the one right and the other left-handed. They have the same number of turns to the inch, and the inside screw I moves, within the tubular screw M, in a thread adapted to it. When, therefore, we turn the nut E, the one screw moves forward and the other backward. They separate,

the other screw to another plate. Each of these plates contain a small semicircular lens, K and L, and when these plates are together, the lenses are together. The movement of the screw separates the centres of these lenses, and the amount of separation is measured by the number of turns, and parts of a turn of the graduated circle F. As, however, it would be troublesome to keep account of these, a very small mother-of-pearl plate, G, is attached outside to one of the inside plates, and is graduated so that one division upon it is passed over in one turn of the screw.—When the dynamometer is used, it is held in such a position near the eye-glass whose power we wish to test, that the image of the object-glass may be distinct within it. The screw of the micrometer is then carefully turned, until the two discs which immediately begin to show themselves just touch at their outer extremity. Their position being noted, the same operation is repeated by again turning until the two just touch at the other side, and the number of turns and parts of turns are again noted. As the discs move equally, the space passed over during each motion, will correspond to the magnitude of the disc, and the mean of the two will be that magnitude, corrected for errors of the scale. As it is of great importance that the semicircular lenses should only separate at the line of their centres, not letting that line change in direction, a horse-shoe spring, O, is adapted so as to press against the plates, and to keep them properly adjusted. This micrometrical method admits of very great accuracy. The dynamometer is applicable to any telescope on whatever principle constructed.—Although not strictly a dynamometer, the method proposed by Gauss for determining the magnifying power of a telescope may be mentioned here. If we invert the telescope, and direct the eye-piece toward some distant object, then, on looking through the object-glass, the image of this object will appear as many times reduced in size as it would be magnified by the telescope, if we observed through the eye-piece. The telescope then is directed so that two objects can be distinctly seen through the object-glass in the middle of the field of view, or at equal distances from the optical axis. A theodolite is now directed towards the telescope, so that the optical axes of both coincide, and the angle α , formed by the two foregoing objects, is measured by the theodolite. Next, remove the telescope, and measure with the theodolite the angle A really comprehended between the objects themselves. The required magnifying power, m , is—

$$m = \frac{\tan. \frac{1}{2} A}{\tan. \frac{1}{2} \alpha}$$

or, if A and α are small, it is simply $= \frac{A}{\alpha}$.

Other modes of accomplishing the same object are given in all works on practical optics.

therefore, by double the motion of either. Now, suppose the one screw attached to one plate and

Dynamics. That portion of abstract or purely deductive Science which takes account of the habitudes of a point or body as to Motion, when that body is acted on by any System of Forces, has with great propriety been designated **RATIONAL MECHANICS**. But the habitudes in question are of two distinct kinds:—either the System of Forces acting on it, will keep the point or body at *rest*, or it will impress on it a definite motion. To determine the conditions and relations of Forces that produce rest, or which are internally in *equilibrio*, is the function of **STATICS** (*q.v.*): to determine the direction and amount of motion which any System not in equilibrium, will impress on a point or body under any given circumstances, is the province of **DYNAMICS**. At the foundation of both departments of Inquiry, rest certain recognized results usually termed the **LAWS OF MOTION**,—a most important subject, discussed in this dictionary under an article with that name. Departing from these Laws, the entire fabric of *Rational Mechanics*—alike *Statics* and *Dynamics*, is essentially deductive.—Without attempting to enter on details, we shall now briefly sketch, under a few heads, the leading contents of *Dynamics*,

(1.) *Dynamics, fundamental conceptions of: Different kinds of Motion; their characteristics and the mode of expressing them.*—There are two grand classes of Motions—*uniform* Motions; and *varied* Motions, or Motions whose rate is *accelerated* or *retarded* according to some function of the *Time* during which they exist. The characteristic of the former class is simple, and easily expressed,—consisting merely in the fact, that *the spaces described by a body in uniform motion are proportional to the times of description*: and the whole habitudes of a body under the influence of a motion or of motions of this description, are immediate results from the **LAWS OF MOTION**, and their **COMPOSITION** (*q.v.*) The only point of difficulty, then, connected with the conception and expression of *Motion*, has reference to the case of *Varied*, i.e. of *accelerated* or *retarded* Motions; and it is to this subject alone—one in which we owe the first and all-important step to Galileo—that our present remarks are addressed. These remarks are restricted, further, to the case of accelerated motions; for, since a retardation may be considered as a *negative* acceleration, it is manifest that the laws of the one class are virtually included under the laws of the other. One other preliminary statement: A body, however accelerated, will generally be found moving under the influence of two forces or causes of motion, a force causing an uniform motion, and a force causing a varied motion. These, however, may be separated: i.e. the space which the body would pass over in a given time in obedience to the uniform force, may be calculated apart; and also the space it would move over in the same time in obedience to the accelerating force: the sum of these spaces

will plainly be the entire space through which the body has moved in that time. The question thus simplified may now be enunciated as follows: Suppose a body to become subject to an accelerated motion, how shall we express or compute its habitudes—viz., its velocity at the end of a given time, and the space it has traversed in that time? The simplest case is that of *uniformly accelerated* motion, or that motion which receives an *equal increment* in an *equal time*; one, however, already so fully discussed under article **ACCELERATED MOTION**, that we can dispense with further elucidation here. The laws, as there unfolded, are certain, definite, and manageable, so that in so far as this fundamental conception of Dynamics is concerned, or the modes of expressing and dealing with it, there remains nothing to be desired. It is the case, as the sagacity of Galileo discerned, of *falling bodies*; and, indeed, the only form in which accelerated motion is presented by the phenomena of Nature. All other and more complex descriptions of accelerated motion,—motions in which the acceleration takes place according to other functions of the *time*,—are, therefore, purely hypothetical; but should consideration or discussion of any such ever be required, the *Infinitesimal Calculus* will be found quite as capable of representing and discussing them, as it is with regard to the actual case just spoken of. No difficulty, whatever, therefore, now encumbers this foundation of general Dynamics; so that we may proceed to survey briefly the nature of the solutions provided by that Science, for all problems concerning the habitudes of bodies subjected in any way to such motions.

(2.) *Theoretical Dynamics. Part I.—The Motion, free or constrained, of POINTS.*—On entering the inquiry concerning the habitudes of Points in Motion, it is easy to discern that it contains two problems—a *direct* and an *inverse*. It may be required, for instance, to determine the shape of the path, which a point must describe, when partaking of various given motions; or, the shape of the path being given, it may be required to determine those separate motions or forces under influence of which the point may describe that path. An instance of the first problem is this,—given the impulse which a projectile receives, and, assuming the laws of falling bodies, to determine the curve described by the projectile? An instance of the second problem is presented by the phenomena of the solar system, viz: the planets describe *ellipses* around the sun,—required the forces that cause them to describe that path? Throughout the whole of the Science of Dynamics, this division into direct and inverse problems necessarily prevails; but as the inverse solution depends for its methods on the conceptions contained in the *direct* one, we shall restrict ourselves here to consideration of the latter. It ought to be remarked, however, that it was by laying the foundation, and in so far-completing

the solution of the inverse problem, that Huyghens and Newton obtained their unwithering laurels. A Point, under the influence of continuous forces, may either be *free* to move through space as these forces shall direct it, or it may be *constrained*, i.e. it may be restricted to motion on some plane or curved surface, to which it is attached, (for instance, it may be free only to slide along the surface of a table, or the convex surface of a globe, &c.) Hence two classes of Inquiries regarding the motion or the path of a Point. Dynamics furnish the complete solution of both.—I. The method of treating the case of a free Point, which is now generally adopted, is due to Euler. Taking each force separately, the *instantaneous action* of that force on the point or molecule, is decomposed—by the theorem of the decomposition of Forces—into three others, along the three usual rectangular co-ordinates: and by adding together the corresponding components of all the actual forces, we reduce them to three continuous forces acting on the molecule, along these co-ordinates. If, then, the total force along the axis x be named X ; the force along the axis y , be named Y ; and that along z , Z ; we immediately obtain, in accordance with the laws of accelerated motion, the following equation for any time t ,

$$\frac{d^2x}{dt^2} = X. \quad \frac{d^2y}{dt^2} = Y. \quad \frac{d^2z}{dt^2} = Z.$$

And also—

$$v^2 = 2 \int (X dx + Y dy + Z dz),$$

from which equations, the co-ordinates which *define the nature of the curve*, and the law of the velocity of the molecule in it, may be deduced by mere analytical methods. In the more complex cases, the analytical difficulties (like everything depending on *integration*,) are often very great: indeed, it has been, by the efforts requisite to overcome such difficulties, as presented by dynamical problems, that Analysis itself mainly advanced:—the purely-dynamical portion of the problems rarely opposes serious obstacles to the inquirer.—II. If the point is not free, but so attached, let us say, to a curve surface, that it cannot depart from that surface, the problem becomes more complex, although there is less difference between the two cases than at first appears. We have only, indeed, to account as one of the continuous forces, acting on the molecule, the *total resistance* offered by the given surface: and the one problem then becomes identical with the other. The difficulty resides in the right analysis of that resistance. Now this consists of two parts quite distinct, and which may be distinguished as the *Statical* resistance, and the *Dynamical* resistance. The statical resistance is that which would take place if the molecule remained motionless; it is the resistance of the surface to the pressure of the molecule upon it at any

instant; and, therefore, must be effectively equal and opposite to the energy with which the continuous force that acts on the molecule, presses it down on the curve at that instant—an energy easily expressed by aid of the theorem of the Composition of Forces. The *dynamical* resistance, on the other hand, has quite a different origin; it is engendered by the *motion* of the point; and results from the tendency of every body to abandon the curve it is forced to describe, and to follow, at every instant, in obedience to the First Law of Motion, the direction of its *tangent*. This peculiar resistance is, of course, always and necessarily manifested, when the point passes from one element of the curve surface to the next element; and a few simple considerations enable us to arrive at the theorem, that the *centrifugal force* is always equal to the square of the effective velocity of the moving point, divided by the radius of curvature of the curve surface at the instant in question. The *direction* of this special form of resistance is as easily obtained as its *intensity*: and when it is compounded with the *statical* resistance described above, we have that total new force, to which, because of its connection with the surface, or because of its *constraint*, the point or molecule is subjected. Joining that force of resistance to the other continuous forces, we reduce, as already stated, the case of a *constrained*, to that of a *free* Point.

(8.) *Theoretical Dynamics*. Part II.—*The Motion of a rigid system of Points or of a SOLID BODY*.—The problem just analyzed is plainly nothing more than an abstract one; and its value consists in its being the necessary foundation of all actual or real inquiries. Nothing exists in nature, similar to the motion of free or constrained points. We have to do, in real exigencies, with *bodies*, or rigid systems of points; and it is quite clear that no *body* in motion can be treated as a simple point, just because the mutual actions and reactions of the several parts or points of which it is composed, must necessarily modify, and—it may be—greatly change the motion that would be assumed by any of these points taken separately, and affected by the continuous forces at work upon the bodies. To rise from the abstract problem to the real one is, therefore, the aim of this second section of Theoretical Dynamics; and the honour of establishing a general and adequate method is due to D'Alembert. Previous to the labours of the great French geometer, each new set of problems belonging to this class was treated by aid of a separate general principle—as it was called—some principle peculiarly applicable to the questions under consideration; and this was the origin and object of all those separate *principles* in Dynamics, which are in reality only general *theorems*, well adapted to the treatment of the kind of problems in which they primarily originated. D'Alembert put an end to the reign of these special theorems, by taking account directly of the dynamical meaning of the action

and reaction of moving rigid systems of points, and expressing that in a general equation. See **ALEMBERT, D', PRINCIPLE OF.** The character of this famous principle may be stated once more. "When, by the reactions which several points exert on one another through effect of their connection, each of them takes on a motion in obedience to external forces, different from what it would have done, were it single and *free*, this *free* movement may be considered as composed of two others—the movement which actually takes place, and the movement which, through that connection or constraint, has been destroyed. Now these destroyed movements will be found, in every system, to be of a contrary character,—some of the points actually moving swifter than they could have done *freely*, and others more slowly. D'Alembert's principle is that these destroyed quantities of motion—the one set *positive*, the other *negative*—necessarily balance each other." The student will easily recognize that, by aid of a principle so simple and comprehensive as this, all problems involving the action and reaction of a system of rigid points, are at once reduced—in as far as these reactions or that rigidity is concerned—within the sphere of problems of equilibrium; and Lagrange accordingly, in his immortal work, the *Mecanique Analytique*, has combined D'Alembert's theorem, with the Statical *Principle of Virtual Velocities*,—thus raising the science of Dynamics to its highest logical perfection. We may conclude, therefore, with regard to this second part of Theoretical Dynamics likewise, that it now presents no speculative difficulty.

(4.) *Theoretical Dynamics.* Part III. *Motions of Rotation.*—A system of rigid points may be subject to two descriptions of motions—to one or the other, or both,—that in themselves are altogether distinct. It may undergo *translation* through space; or it may *rotate* around some point within itself; or, while being *translated*, it may also *rotate*. The habitudes of the body as to both motions, may indeed be investigated by one general method; but the consideration of these motions *apart*, has recently tended greatly to the simplification and rationalizing alike of Statics and Dynamics; and the method of doing this is unquestionably due to M. Poinso. The way to this signal advance in method, originated with the great and ever-fertile Euler; so that, after his time, the complete analysis of the movement of any system, acted on by any forces, consisted in determining, *first*, the velocity of its centre of gravity and the direction along which it is being translated; and, *secondly*, the direction, at each instant, of the spontaneous axis of rotation passing through the centre of gravity, and the velocity of the rotation of the system around that axis. To effect this latter task *directly*, Poinso proposed his theory of *Couples*, and thereby gave a positive and real significance to three of the six general equations of Equilibrium. The real

bearing and significance of Poinso's doctrine are exposed fully under articles **COUPLES** and **STATICS**, *q.v.* And the student is especially referred to recent memoirs on Rotation, by that perspicuous writer, for evidence of the great simplicity with which a subject, once so difficult and even intractable, is now invested.

(5.) *Dynamics, General Theorems in.*—Reference has been made above, to those theorems—*special* theorems they ought to be termed—which in the course of the progress of science have been welcomed and rightly valued because of their applicability to various classes of researches. The following are the chief that belong to Dynamics:—1. The principle of the *Conservation of the Movement of the Centre of Gravity*,—discovered by Newton, and demonstrated at the beginning of the *Principia*.—2. The principle of *Areas*,—the first idea of which we owe to John Kepler, and which, as generalized by D'Arcy, must be accounted one of the bases of our Celestial Mechanics.—3. The principles of *Moments of Inertia*, and of the *principal Axes*, discovered by Euler.—4. The *Conservation of Living Forces* (*virium vivarum*), suggested by Huyghens and completed by John and Daniel Bernoulli.—5. The principle of Maupertuis, erroneously named the *Principle of the least Action*.—And, 6th and last, The principle of the *co-existence of small oscillations*, a very admirable discovery by Daniel Bernoulli.—All these, as well as certain statical theorems of the same order, will be found explained under appropriate heads in this volume.

(6.) *Dynamics, Practical Problems of.*—The student has now been presented with an outline of the principles and methods of pure or abstract Dynamics. We shall merely enumerate, in conclusion, a few of the actual problems to which these methods are applied. *First*, we have the subjects of *Impact* and *Collision of Bodies*. *Secondly*, the theory of *Projectiles*. *Thirdly*, such problems as those of the descent of bodies in *Planes* and *Curves*, the characteristics of motion and oscillation through *Cycloidal* arcs, the *tautochronous Curve*, the *Curve of Equal Pressure*, &c., &c. *Fourthly*, the entire domain of the Celestial Mechanics, which abounds, in every portion of it, with illustrations of the inverse as well as the direct problem of *Central Forces*. *Fifthly*, problems connected with oscillation and motion about a fixed axis, such as the *Compound Pendulum*; the *Centres of Oscillation* and *Percussion*; permanent *Axes of Rotation*; the *Figures of Rotatory Bodies*; *Axis of Spontaneous Rotation*; *Impulsive Action on a Rigid Body*; the action of *Resisting Media*, &c., &c. And, *Sixthly*, the most difficult and imperfect of all—the subject of *Hydrodynamics*. It cannot be doubted that the general formulæ of pure Dynamics are applicable to the movements of any set of particles, whether these constitute a fluid, a gaseous, or a solid body; and that, to insure their practical

application, we only require to know and to be able to express aright, the relations connecting these particles among themselves. The real perplexity of the case of fluids and gases rests in finding an expression of this sort that will be at once correct and manageable; and it must be confessed that, when an attempt is made to express fully the condition of liquid particles, the resulting equations are so unmanageable that geometers have been fain to resort to hypotheses representing the fluid or gaseous condition so imperfectly, that no faith can be placed in the results obtained. The general science of Hydrodynamics remains, therefore, considered as a practical one, still in its infancy; and we are obliged to deduce its theorems and laws, by processes that are purely empirical.—See the various articles indicated above. The student who desires to pursue the subject is recommended in the first place to the *Mechanical Euclid* of Dr. Whewell, the treatise on *Statics* by Poincot, the two excellent and perspicuous volumes on *Statics* and *Dynamics* by Mr. Earnshaw; and the *Mécanique* of Duhamel. Other valuable works on the subject as a whole, as well as on its several parts, abound alike in French, and in our English Scientific Literature.

Dynamotica, Vital, is the application of the principles of the Dynamical Theory of Heat (see **HEAT**) to organisms endowed with life, whether animal or vegetable. Animals are regarded as machines for the economic development of energy; plants, as storehouses of energy. The natural tendency of the mind is to view living creatures as original centres of force—matter being permeated by a peculiar, independent power, flowing from life. But life is rather a dispenser than a source of force. Left to itself, it languishes and ultimately dies out. Its stores are extraneous, in the food we eat. So long as this is supplied, the animal develops force, whether of heat or of work, and in exact proportion to the supply. When we move a leg or arm, we use only the common mechanical arrangement of bands and pulleys, by which we would communicate a similar motion to a piece of dead matter. As we can trace the motion of the straps and wheels of a factory to the chemical action going on in the furnace beneath the boiler, so we can see the origin of the force which moves the bands and pulleys of the animal machine in the chemical action to which the food is subjected. In the former case, however, every step in the transformation of energies is clear; in the latter, the mysterious conservative power of life interrupts our analysis. This chemical action seems divisible into *general* and *special*. General chemical action results chiefly in heat, and is independent of the will: special is that which accompanies muscular exertion, and is usually confined to the seat of this exertion. The relation of general and special chemical action to each other and to the evolution

of force is not so well ascertained. Animals form one of three media by which chemical force may be evolved—the other two being the electro-magnetic engine and the various forms of thermal engines. To produce ultimate useful work by the electro-magnetic engine, chemical force assumes the form of electric force; while in thermal engines it becomes primarily heat. Does the energy of food act through either of these media, electricity or heat? or does it pass directly into the *vis viva* of animal and external bodies? There is nothing in the known phenomena of muscular action to support the latter supposition; and, tried by scientific principles, it is in no way probable. We have no right to introduce a new force, because we cannot clearly see how acknowledged forces can intervene. This would be a return to the profitless system of occult qualities. Is it, then, energy of heat or of electricity which is evolved from animal food, and placed at the disposal of the animal will? "There are at present known," says Thomson, "two, and only two, distinct ways in which mechanical effect can be obtained from heat. One of these is by means of the alterations of volume which bodies may experience through the action of heat; the other is through the medium of electric agency." (*Transactions of Royal Society of Edinburgh*, vol. xvi., p. 542.) But there is no arrangement for thermal expansions and contractions in the body. Muscles generate instead of destroying heat by contraction. Similar reasons may be adduced against the existence of thermo-electric currents in the tissues; and one objection bears against both, that all experiment proves that the chemical forces never develop a *thermal* equivalent in the body. We are, therefore, in the present state of our knowledge, shut up to the conclusion that electricity is the form which the potential energy of food assumes before appearing as visible mechanical effect. Are there any physiological facts in support of this rather abstract conclusion? We know that in every part of the body chemical processes are advancing. We know also, from Faraday's electric theory of chemical combination, that there must therefore be large quantities of electricity present; but whether there is a physical arrangement for "loosening the electricity from its habitation for awhile, and conveying it from place to place," is a question not so easily answered. A full consideration would lead us into all the details of animal electricity, but we shall confine ourselves to such remarks as are necessary for present application. (1.) That the existence of the conformation of bodily parts requisite for the liberation of electricity is quite consistent with the animal economy, we know from its actual presence in various animals, *e. g.*, the *torpedo*, *gymnotus*, &c. Matteucci found in the torpedo a regular electric series of cells, with positive and negative poles; an electric lobe in the brain, from which nerves ramify over these cells, placing

the time and extent of their action under the control of the creature's will. The activity of the electric function is proportioned to that of the circulation and respiration. True, this electricity is applied by the torpedo, and similar animals, to purposes of attack and defence, and not to motion; but still the discharge is entirely under their control, and an electric current may, in other animals, produce muscular contraction and external work. But (2.) free electricity does undeniably circulate in all muscular tissue. We cannot certify ourselves so thoroughly of its source, but the fact of its presence is certain. We are apt to forget the fact in the fanciful and strained theories sometimes set forth in explanation of it. Its amount varies with the mechanical duty of the muscle, and with all the circumstances of circulation, respiration, external temperature, &c., which modify muscular action. At the moment of contraction the current almost entirely ceases, as happens when an electro-magnetic engine begins to work. In each case electricity ceases to exist as such, and passes into the form of mechanical effect. (8.) It is also found that no artificially applied agent excites muscular tissue so strongly as electricity. Matteucci has proved that a given quantity of zinc, consumed in a battery, can be made to do much more work by occasioning muscular contraction, than by turning an electro-magnetic engine. Opinions may differ as to the import of these facts; but while an inquiry into the mode in which chemical becomes muscular force, is necessary to the completeness of a theory of vital dynamics, it does not involve its accuracy. This depends on the establishment of an equivalence between the potential energy of the food and the actual energy of animal heat and work done. In thermo and electro-dynamics, it is easy to exhibit the equation; but here we do not deal with a mere engine, but with a self-adjusting variable organism. The act of overcoming external resistance quickens breathing and circulation. Thus the formula for work done by an animal in any given case becomes complicated.

$$W = J \frac{\theta (a - b) - H}{\theta a}$$

where a is the oxygen consumed during motion, b during rest; H the increase in animal heat following motion; θ the thermal equivalent of the combination of a unit of oxygen with the food; J the mechanical equivalent of a unit of heat. That special chemical action ($a - b$) is almost entirely productive of work, Matteucci proved in the case of the frog. Estimating its mechanical value in the contraction of the gastrocnemian muscles of that animal, he found the work done bear to it the high proportion of .878. The calculation of the element H would have completed the equation. The first application of these principles, though not of this formula exactly, which is difficult to follow in actual experiment, was

made by Messrs. Scoresby and Joule in 1846. (*Philosophical Magazine*, 1846.) According to Watt, the value of one horse-power for one day is 24,000,000 foot-pounds. To sustain a horse in working condition, 12 lbs. hay and 12 lbs. corn are necessary per day; or one grain of this mixed food enables him to raise 143 lbs. to the height of one foot. These gentlemen found that when burned, one grain raised the temperature of 1 lb. of water 0.682° Fahr., a thermal effect dynamically equal to 527 lbs. raised to the height of one foot. The horse, therefore, converts .27, or nearly one-fourth, of the entire *vis viva* of his food into useful mechanical effect. From the absence of any definite standard estimate of man-power, calculations as to its economy are not so determinate. Thomson seems to have made the first attempt. (*Philosophical Magazine*, S. 4, vol. iv.) He thinks it probable that a man, by walking up-hill eight hours a-day, may turn one-sixth of the mechanical value of his food into work, and one-fourth by such labour as pumping for six hours per day. In the former case, the work is foot-pounds of his own body; in the latter, foot-pounds of water raised. The general conclusion of Scoresby and Joule is, "that the animal frame, though destined to fulfil so many other ends, is, as an engine, more perfect in the economy of *vis viva* than the best of human contrivances." The student will find materials for more elaborate calculations in Gavarret's treatise, *De la chaleur produite par les etres vivants*.—It is proved from these investigations that the chemical forces of food are the source of the energy of all animals. But whence this chemical force? Since the ultimate food of all animals is vegetable, this leads us to the *Vital Dynamics of Plants*. The growth of plants consists chiefly in a decomposition, against the force of chemical affinity, of carbonic acid, water, and ammonia, imbibed from earth and air. This is, in fact, an *unburning* of the fire which has burned on our hearths, in our furnaces, and in the bodies of animals—a restoration of the materials there consumed to their former state of combustibility. The potential energy of carbon, hydrogen, and oxygen, is returned; or, in other words, actual energy has been expended in separating these elements. Actual energy of what? *Vegetable respiration*, as this process is called, the converse of animal, has been proved by the experiments of Ingenhouz, Senebier, and other investigators, to be a process which depends on light. It ceases on the coming on of darkness, and there supervenes a slight reverse action, one of combustion. It is therefore actual energy of sunlight which overcomes chemical force, and becomes potential energy, to be released as actual energy once more in our fires and bodies. When we decompose water, i. e., separate oxygen and hydrogen by force of electricity, we exchange electric power for the tendency of these gases to unite (potential energy), and this tendency is

satisfied by applying a light to the gaseous mixture. An explosion ensues. We get water as before, but besides, heat the equivalent of the electricity. So the force of a small fraction of the infinitesimal luminiferous wavelets which originate in the sun is made latent in the affinities of separated oxygen, hydrogen, and carbon. When these reunite, we get carbonic acid, and water as before, but besides, heat, or electric or vital force, the equivalent of the light-power expended. An ingenious calculation of the amount of sunlight and heat which is thus economized has been made by Professor Thomson (*Phil. Mag.*, S. 4, vol. iv.) Estimating the mechanical value of the annual produce of an acre of forest land from Liebig's data, and the mechanical value from Pouillet's data, of the sunlight falling on that space at the latitude of Giessen, he finds that "probably a good deal more than $\frac{1}{1000}$ of the solar heat which actually falls on growing plants, is converted into mechanical effects." Here certainly is poetry enough thrown around the commonest objects—our coal fields, our street lamps, our steady oil, our home hearths, our furnaces; for the sunshine which fell on an unpeopled earth lights us and works for us with the sunshine of to-day.

Dynamometer. An instrument constructed to measure the work done in overcoming a given resistance and causing a given motion. The name signifies a measure of power or force. The instrument is rather a measure of effort or work. We conceive a force as being something instantaneous, at any moment changeable, beginning or ceasing. On the other hand, we conceive of work, as the operation—through spaces of time—of forces. If we pull a body, for example, along a level road, we exercise a certain force every moment that we continue our work; but the work, though depending on the force, does not depend on it alone. If, for instance, we pull another body with only half the force, over twice the distance, we do the same amount of work. Work, therefore, depends upon the force applied and the space through which the body on which it is performed moves; and the dynamometer proposes to measure the work, in any case of resistance overcome and motion produced. Assuming the obvious principle, that work will be measurable by the product of the force, if kept uniformly acting, into the space through which it acts, we may come to see upon what dynamometers must depend. They require to provide a measure of the force, and a measure also of the space through which the force acts. If the force continue uniform during the whole action, we should find the problem sufficiently easy. The space traversed by a moving body is easily measured, and very many contrivances might be easily applied to such a body to make it self-registering as to this point. If, then, we are able to measure the force with which it moves, the desired result will be obtained. If we cause it to act, for example, in pulling out a

spring, we have a measure, in the distance to which the spring is drawn out, compared with the amount of *gravity* capable of drawing it out to the same distance, when a weight is hung upon it. We have then simply to multiply the two values just discovered one by the other, for the required result. The original dynamometers (as Regnier's) limited themselves to determining the value of the force, and left out the other element as unimportant. And, in fact, it might be considered to be so pretty fairly, were the usual case such as we have described. If the force remained steadfast, we should have merely to measure the whole space and the one force. But in ordinary mechanical cases, our working forces do not remain entirely, in many not even approximately the same, throughout intervals during which we desire to measure the work. We have, therefore, to take the small spaces during which they do remain comparatively steadfast, and to multiply these by the forces operating during motion through these spaces, and sum up the amounts of work obtained in each, in order to arrive at the total value. If all these small spaces, during which the force may be considered constant, were equal, we might still adhere to the measurement of forces merely. We could take the average of all the forces successively measured, and multiply the average by the total space. In fact, calling F' , F'' , &c. the forces, and s the small spaces, ($M s$ being the whole space, which is divided into M parts all equal), we might estimate the work as already shown by $F' s + F'' s + F''' s + \&c. = s (F' + F'' + F''' \&c.)$ The method just indicated takes for this measure $M s \times \frac{F' + F'' + F''' + \&c.}{M} = s (F' + F'' + F''' \&c.)$

which is, therefore, equal to the true value of the work. But as $M s$, the whole space, is easily measurable separately, these original inventions, confined to measurements of F' , F'' , &c. would therefore have given very simply the results required. Leroy's construction of dynamometers was exactly like our present letter weights. The force whose measure was required, was made to push a spiral spring inside a tube, downwards; and then compared with the force of gravity acting on known weights able to compress the spring to the same extent. Regnier's construction was an elliptical spring, to be pushed into greater curvature or drawn into less by the force applied; and latterly, two plates of steel, one of which was kept fixed, and the other moved from or to it by the force. These constructions—though perhaps both susceptible of mechanical improvements, which they never attained—become immediately incapable of measuring work when the spaces through which the inconstant forces move become themselves inconstant. The expression for the total work—calling s' , s'' , s''' , &c. the successive unequal spaces, becomes $F' s' + F'' s'' + F''' s''' \&c.$, an expression which requires, for the determination of its total value, a simultaneous measurement of the

quantities indicated by F' , &c., and s' , &c. And a new difficulty likewise occurs. In ordinary cases, the variations of these two inconstants are very rapid—so rapid that we could not read them off, even if noted by the instrument, without inconceivable labour. It is therefore essential that our instruments should themselves be made to keep a register, afterwards to be examined at leisure, of the values which they render perceptible. If, for example, we can succeed in making our dynamometer put a mark down of a certain length proportional to the force acting at the time, for every force which it measures, and if we can get it to move the paper, or ourselves move it, so that these marks will be placed in the true order of succession of these forces, we will have a sheet, when the paper is taken out, exhibiting the series of the F quantities. If, still further, we have a simultaneous arrangement which shall mark the spaces through which motion has taken place, we shall draw out a sheet similarly marked with the successive values of the quantities s ; and taking the two series together, we shall obtain $F' s' + F'' s'' + F''' s'''$, &c., or the whole amount of work done. We shall endeavour to indicate in a general way how various dynamometers accomplish these objects. The ordinary spring dynamometer consists of two rims of steel of the parabolic form—the one kept fixed in the instrument—the other fastened to it at the two extremities, but drawn out from it to certain distances by the successive forces. The distance of the middle points of the two springs, when the one is pulled out in this way, indicates the amount of force. If a pencil be attached to the centre of the moveable spring, it will move with it, and indicate this distance. But this would give us only a pencil moving up and down a straight line; and neither the various successive values of the forces, nor the order of their succession, could be at all distinctly indicated. If, however, the paper was made to move beneath the pencil, the distance between the two points might then be given continuously; and all changes would be marked regularly in the order of their succession. Through means of

such an arrangement, we might have such a figure described by the pencils as above.

The curved line would be described by the pencil attached to the moveable, and the straight line by one attached to the straight spring. The perpendiculars $P^1 T^1, P^2 T^2, P^3 T^3$, &c., represent the successive forces, and the distances $T^1 T^2, T^2 T^3$, &c., the distances for which they approximately act. If we take a very narrow step like $T^1 T^2$ for the space, the force may be considered as either $P^1 T^1$ uniformly, or as $P^2 T^2$ for these lines, and the inner ones representing the forces will differ excessively little from one another. The area, then, which we may call $T^1 P^1 s^1 s^1$, may be expressed by $P^1 T^1 P^2 T^2$. Similarly, the area $P'' s''$ might be expressed by $P^2 T^2 P^3 T^3$, and so on. Hence, the whole sum of the work done in any given space would be the sum of the similar rectangles, &c., throughout that space. It is very clear that the smaller we take these spaces, and the more of them, therefore, the more correct will our appreciation be of the total effect, and that each approximation will come, therefore, nearer to giving a sum equal to the value of the area enclosed between the line TA and the curve AP . The area of the curve will, therefore, give an equivalent for the whole work, and the area between any two of the quantities $P T$ will give the similar equivalent for the portion corresponding. Sometimes it is of more importance to get the average force wrought with during a given time than the total work done. In this case, the method found useful is to put a chronometrical arrangement in connection with the machine, so that the paper may be drawn uniformly. And it might be without difficulty demonstrated, that the area of the curve divided by the length AT would give the mean force for the whole action. This curve would now, however,—unless there had been uniform motion before—be a different one from the curve AP , though similarly described; and, therefore, except in this case of uniform motion, the value of the force, or even of the average force, would not be a sufficient index of the total work done during a given space. Such is the principle upon which the dynamometer always depends. Peculiar modifications of the arrangements described would be necessary to fit it for application to rotatory motions.—The parabolic form is used for the spring commonly employed in the dynamometer, in order that the force may be as equally as possible distributed over the curve, and that the resistance may be proportioned to the force. —Watts' Indicator is a species of dynamometer of special application, which we shall describe under that word.

Ear. Little is known regarding the physical significance of that singular and apparently complex apparatus which constitutes the *Ear*. In Man, as with most animals gifted with hearing, it consists of an outer organ, that may serve some such purpose as an ear-trumpet, viz., to collect sound; next, of a tube through which the vibrations pass inwards; then, of that elastic membrane, or drum of the ear, which would seem sensitive to all impulses; and lastly of a cell and a chain of small, singularly-shaped, and unintelligible bones, conducting towards the place where traces are first found of the presence of the auditory nerve. Anatomy and Physiology have described this remarkable apparatus, but they have thrown no light whatever on the relation and purpose of its various parts; nor can physical science at present offer them the slightest aid. But in whatever way its constituent parts may act, it cannot be doubted that the human ear is an instrument of remarkable delicacy and great compass. All sounds, it is well known, travel through space with the same velocity. They differ only in the lengths of the waves or undulations that occasion them—the lengths increasing as the *graves* of the sound increases, and *vice versa*. Now, it has been distinctly established by aid of Cagniard la Tour's Siren, and Savart's arrangement of *toothed wheels*, that the gravest or lowest sound which the human ear can ordinarily discern, is one made by a body vibrating only *fourteen* or *fifteen* times in a *second*; while the acutest audible sound demands for its production no fewer than *forty-eight thousand vibrations* in the same space of one *second*. The immense interval between these numbers, is the measure of the range of the phenomena of sound, of which our organ of hearing can take cognizance. The interval is vast indeed; and within it, lie the causes of those sounds which Nature utters, and all the innumerable Harmonies and Melodies evolved by Scientific Art. Still, that which we discern is only one domain of Sound. Our Ear penetrates so low, that few grave sounds can exist, of the recognition of which it is incapable; but, at the other end of the scale, how great and even interminable the range from which it is shut out! Dr. Wollaston was certainly correct, that the Ear, fine as it is, as well, perhaps, as every other human sense, is adjusted to the discernment only of one finite and allotted span within an infinite Universe.

Earth, The, ♂—the globe we inhabit; the third planet in order from the Sun; and the largest within the belt or ring of the Asteroids. Its equatorial diameter is 7,926 miles; its polar, 7,896 miles; and in density, it is 5.67 times heavier than water. The mass of the Earth, compared with that of the Sun, is .0000028173. Its mean distance from the central luminary is

about 95 millions of miles—a space through which light occupies 8 minutes 18.8 seconds in travelling; but, as the eccentricity of its orbit is 0.0167751, if this mean distance be termed 1, the distance of the Earth at aphelion will be 1.0168, while at perihelion it is only .9832. The quantities of light received by it in these opposite positions are in the proportion of 0.967:1.084. The period of the revolution of our globe in its elliptic orbit is 365.2568744 mean solar days, or 365 days, 6 hours, 9 minutes, and 10.75 seconds. Its *tropical* revolution, or the period elapsing between vernal equinox and vernal equinox (that is, the period of the revolution of the *seasons*) is 365.24222 mean solar days, or 365 days, 5 hours, 48 minutes, 47.81 seconds. The Earth rotates on its axis in one *sidereal day*, or 24 sidereal hours; that is, in 23 hours, 56 minutes, and 4 seconds of *mean time*.—We proceed to refer briefly to the points of chief interest concerning our Planet's *motions*, its *magnitude* and *figure*, its *density*, and its *temperature*.

(1.) *The Earth, Motions of.*—The chief of these are the annual *Revolution* in an orbit, and the diurnal *Rotation* on an axis. The Earth's velocity in its orbit varies, according to Kepler's Law of the Conservation of *Areas*, modified by certain *perturbations*, of which an account will be found in detailed works on Astronomy. The angular velocity of Rotation is absolutely uniform. Besides these, certain motions affect the Earth's axis itself, the nature of which is explained under PRECESSION and NUTATION. The point to which we desire to draw attention here is this—How is the reality of these motions established? Living on the surface of the Earth, and, therefore, moving through space along with it, we cannot see these motions *directly*. How, then, are we assured of their existence as a *fact*, as distinguished from a serviceable *hypothesis*? If these motions are real, doubtless they will impress *apparent motions* on all bodies external to the Earth. For instance, the rotation of our globe on its axis would produce an apparent diurnal revolution of the celestial vault in the opposite direction; and so, with our motion of revolution. Such external motions undoubtedly exist. That grand and familiar daily and uniform revolution of the whole sidereal host, is the very phenomenon which would manifest to a spectator on the Earth the rotation of his own globe. Nevertheless, how can it be ascertained that the revolution of the stars is an *apparent* one?—by what kind of considerations are we entitled to attribute it, to an actual but unseen and unfelt Rotation of the Earth as its *cause*? When the immortal Copernicus first attacked the time-consecrated conception, that our globe is motionless, and the prime centre of all things, he could indeed propose his own view only as the *more*

probable hypothesis. It was easy to show that the position of our world as a planet moving around the Sun, demolished at one blow the whole of that artificial Ptolemaic machinery—a machinery that in the hands of Purbach had acquired a complicity with which imagination could never cope; and surely it seemed easier to conceive one little globe turning daily around an axis, than that all these myriads of stars should partake of one and the same motion, with a regularity so rigorous and unbroken. The demonstration of the *fact*, however, was not within reach of science, in these early days, but rather has been reserved in the main for our own. —I. The first actual verification of the orbital motion of the Earth is due to Bradley. His capital discovery of *Aberration*—a discovery already described in this Dictionary (ABERRATION),—furnished a proof almost decisive of the Earth's planetary motion; at least phenomena were detected, and in this way finely accounted for, that could be explained in no wise by the conflicting theory. One difficulty—the difficulty started by the eminently *practical* Tycho—alone remained. If the Earth shifts its position in space, so that at one season of the year it is removed by the immense distance of 190,000,000 miles from its position at the opposite season, why—as the illustrious Observer of *Uraniburg* inquired—do the fixed stars always appear in the *same direction* from us—why have these orbs no *parallax*? The objection could not in any case have been conclusive, because the allegation on which it rests, had no title to be received as absolute. Tycho had no right to assert that the fixed stars *have* no parallax: all that he knew was that his instruments did not enable him to detect any. But the actual discovery of parallax—that greatest triumph of modern observation—(see STARS, FIXED)—has established a positive argument on behalf of the orbital motion of our Planet, of irresistible force. In so far as this motion is concerned, then, the Copernican theory rests on mere hypothesis no longer.—II. In reference to the Earth's *Rotation*, that too has received, although only in very recent times, a demonstration quite as full, and even more palpable and convincing. The existence of a *diurnal aberration*, of which there can be no doubt, might have seemed equally applicable in this case; but it never could be rendered satisfactory, because of its very small amount. All that is needed, however, has recently been amply attained, through a consideration of the necessary *influence of the Earth's rotation, on the apparent motion of bodies situated on its surface*. This has been made manifest in three ways:—(1.) Were the globe motionless, or not rotating, it is clear that a body let fall from the summit of any perpendicular altitude, would fall to the surface, exactly at its foot. But if rotation exists, this will not hold. A body at A, for instance, must, when let fall, continue animated during its fall to the surface *c'* by the

horizontal velocity which it possessed while attached to the top of the height *ca*: in other words, if *A A'* be the space through which, in virtue of the Earth's rotation, the point A would move in the time that a detached part of it would take to fall through *A c*, that detached part will retain, though detached, its original velocity, and when it reaches the surface will have moved over *c B*, a space equal to *A A'*. But *c*, the foot of the perpendicular height, will (as is evident from inspection)

FIG. 1.

have moved in that time only through *cc'*: so that, when the body falls, it will not be at the foot of the tower, but in advance of it by a quantity *c' B*. The necessity of such a deviation towards the east has long been discerned; but the credit of establishing its reality, is due to M. Reich of Freyberg. Taking advantage of a mine of the depth of 520 feet, he repeated experiments in the most careful manner, and quite established the existence of the deviation; and the satisfactory character of the result appeared further from this, that the *amount* of the observed easterly deviation differed from the theoretical amount only by the inconsiderable quantity of .08 of an inch.—(2.) Still more striking, however, are the most ingenious methods of M. Foucault. The sensation is not yet forgotten that was created by his famous *pendulum experiment*. Its principles are as follows: Suppose a pendulum suspended *over either Pole* of the Earth from a point detached from the Earth and set in oscillation. The rotation of the Earth beneath it, can in nowise affect or alter the *plane* of that oscillation; but as a spectator on the Earth, carried round by the rotation of the Earth, would pass first under one end of the pendulum, then under the other, the plane of oscillation would necessarily appear to him to *make a revolution from east to west* in the precise time in which the Earth really rotates from west to east. It is not necessary that the pendulum be suspended from a point detached from the Earth. The attachment of the point of suspension to the Earth, provided it be over the Pole, would only twist round the wire, or cord forming the rod of the pendulum, and make the *ball* itself rotate on its axis in the course of a sidereal day. Next, imagine the Pendulum suspended *over the Equator*. It is equally clear that no apparent revolution or change of the plane of oscillation could take place in this case, just because the spectator at the Equator could not, by being carried round, be brought nearer one end of the plane of oscillation than the other. *Lastly*, let us examine the case of a pendulum at an

intermediate Latitude A , no being the Equator, and po the polar axis of the Earth. The actual

FIG. 2.

rotation of the Earth around po may be imagined the resultant of two rotations, into which two, it can (see COMPOSITION OF FORCES) be decomposed. For instance, if no be taken to represent the true velocity of the Earth around its axis, we

may imagine that velocity and direction, given to it by two rotations—one with the velocity no around po , and the other with the velocity co around ao . But the rotation around po , which is the polar axis of the point A , cannot affect the apparent motions of a pendulum at A , which is the Equator of po . These apparent motions will only be affected, therefore, by a motion of the amount co around ao itself. This latter case is the first one investigated, viz., when the Pendulum is suspended over the Pole; so that the plane of oscillation of a Pendulum at A must, in consequence of the rotation of the Earth, seem to make a revolution in a period of time determined by the velocity co . The time in which that plane will seem to revolve at the place A will be to a sidereal day as $co : no :: 1 : \sin$.

Time of app. revolution = Sid. day $\times \sin$ Lat.
M. Foucault verified his conclusions on a grand scale by suspending a pendulum from the interior of the cupola of the Pantheon; nor does it require more than ordinary precaution, and the use of a long suspension, to enable any one to bring in the same manner, under the notice of any number of persons, this palpable evidence of the Rotation of the Earth.—(8.) M. Foucault has since then imagined a still more ingenious device with the same end—embodied in his GYROSCOPE (q.v.) If a mass be set in rotation freely in space, it will—unless disturbed or constrained—preserve absolutely the plane of its rotation; and, to effect this, it will even overcome slight obstacles. By the mechanical contrivances constituting the Gyroscope, a heavy ring of metal ac , is so freely suspended, that it is almost at entire liberty to turn in any direction. That ring is, while detached—as in the small figure—set in very rapid rotation, and then placed in its frame—a frame so nicely constructed that the heavy ring will continue to rotate for a considerable period, and, as we have said, enjoy, all the while, fullest liberty to assume the position suited to its mechanical condition. Suppose now that a graduated slip on the edge of the apparatus is examined through the telescope ae ; it is clear that if the earth be at rest, the same graduated line will continue under the spectator's eye at the telescope. But if the earth is rotating, and carrying

the Gyroscope along with it, the revolving ring cannot remain in its original relation to the tele-

Fig. 2.

scope, just because its displacement by the Earth would, if it did so, change the plane, in space, in which the ring revolves. To retain itself in that plane, therefore, the ring will cause the graduated slip to move round under the telescope; and the observer will discern the different lines of graduation, passing regularly under his eye, exactly as a star moves across the field of view of a transit instrument. The mechanism peculiar to the Gyroscope, we shall describe under a special article: it is sufficient here to have shown in what manner it fulfils its very interesting object.—Neither the rotation, nor the orbital motion of the Earth, then, can longer be treated as admirable hypotheses—they are established facts.

(2.) *The Earth, Magnitude and Figure of.*—The subjects now referred to, have given rise to as large and interesting a series of researches, as those that relate to any other point of our celestial mechanics. We shall endeavour to notice their chief characteristics.—It is needless to dwell on those familiar considerations that indicate the general shape of the Earth. Multitudes of common phenomena, such as the aspects of bodies seen from a distance—the regular apparent increase and diminution of the altitudes

of stars on the meridian, when the observer travels northward or southward—and, above all, the shape of the Earth's shadow as seen in Eclipses of the Moon,—all concur in proving that our planet's form is globular, approaching, indeed, to a perfect sphere. The *Magnitude* of that sphere is easily determined—at least the methods of determining it may be readily apprehended. Take, for instance, two points on the Equator, so remote from each other, that the one point (because of the Earth's *rotation*) will pass exactly underneath a star, (or have a star *on its meridian*,) exactly one sidereal hour after the same thing has happened to the other. These two points being determined by Astronomical Observation, their actual *distance* in miles may be measured by processes of Geodesy or general Surveying. But as the first of these points moves through the whole Equatorial circuit in twenty-four hours, (the period of the Earth's rotation,) it is plain that the measured distance must be exactly a twenty-fourth part of the entire girth of the globe at the Equator, in other words, a twenty-fourth part of the *circumference* of the terrestrial *sphere*. It is not necessary, however, that the precise space just mentioned should be measured, nor that it lie on the Equator; the accurate measurement of a *degree*, or any part of a degree, of Astronomical Longitude or Latitude, at any portion of the Earth's surface, will answer the same end: nor is there any difficulty in the process, except that which belongs to the exact determination of the distance between the two selected points—a process unquestionably demanding all the resources of practical Geodesy.—The general problems regarding the Shape and Magnitude of the Earth being thus resolved, it remains to inquire whether, with minute accuracy, the *spherical* form can be attributed to our planet. Observation of the figures of our companion planets do not encourage an affirmative conclusion, as their discs are in no case perfectly circular: and, immediately after the discovery of gravitation, Newton discerned that no globe *in rotation* can be expected to be spherical. Suppose, that in such a planet as ours, a canal were cut from the Pole to its centre, and another canal at right angles to it, from centre to Equator; it is clear that, if the planet has assumed a stable form, a fluid filling these two canals ought to be in *equilibrium*; i.e., the weight of fluid in one of the canals should have no tendency to overbalance or push out the fluid in the other. In a planet at rest, these canals would, under such circumstances, be equal in length; and the planet a perfect sphere: but it is different under the condition of a globe's *rotation*. The centrifugal force, affecting in this case the canal from Equator to Centre, and not affecting the one from Centre to Pole, would virtually diminish the *effective weight* or the *density* of the fluid in the former; so that, to produce equilibrium, the *Equatorial Canal* must be *longer than the Polar*.

Newton concluded from these considerations that the Earth cannot be a sphere, but an *ellipsoid*, whose shorter diameter is the polar: and he determined that the actual Polar and Equatorial diameters of the Earth must be to each other as 229:230. However valuable, as a first contribution, Newton's labours could not be expected to issue satisfactorily, either as regards the foregoing numerical determination, or the general shape he attributed to the Earth. Having taken no account of the fact that the density of the Earth in all probability increases, as we proceed from surface to centre, the ratio he gave could not be the true ratio: and although he proved that the Equatorial diameter must be longer than the Polar, he did not prove that the contour of the Earth *must be that of an ELLIPSE*. This latter proposition, indeed, has not even yet received a competent demonstration; nor are Geometers entitled to assert that, in its full generality, it is true. But one positive proposition, of which it is a converse, *is excess*, has been thoroughly established. The excellent Scotchman, Colin Maclaurin, laid down a general theorem, which will always be held a landmark. Clairaut, building on this, proved that in the case of a rotating ellipsoid, a proportion between the major and minor axis, could always be determined, so that—whatever the law of augmentation of density towards the centre—all the particles of fluid filling a canal of any form within it, should be at rest. The successors of these eminent men, advanced—by generalizing and simplifying—their analysis; but, among all their remarkable efforts, it were wrong to omit notice of the classical labours of our own James Ivory. As inquiry proceeds, however, indications increase, that we are not entitled to infer the correct ellipticity of the Earth, or any other rotating planet, as a logical *converso*: nay, recent investigations by Jacobi of Berlin, tend to the conclusion, that other forms of a rotating body, may *also* be forms of equilibrium.—But turning from abstract Dynamical Theory, let us now briefly notice the means employed to ascertain the exact figure of our planet by actual measurement and observation. These are three.—(1.) The geodetic measurement of a degree on the meridian, suffices, as we have seen, to determine the *Magnitude* of the Earth; the measurement of two degrees or portions of degrees, in Latitudes considerably apart, is enough to reveal its exact shape or *eccentricity*. If P E Q E' be an ellipse, it is easy to see that its curvature is much greater about the ends of the major axis than at the ends of the minor—near E or E' than near P or Q . In other words, the osculating or equicurve circle near P will have a longer radius than the same circle in the proximity of E . Let m m' and n n' represent spaces, in those different localities answering to the same fixed number of *degrees*, ascertained astronomically, by the determination of the latitudes of m , m' and n , n' ;

the meaning of which is, that the angle $\pi s \pi'$ —(s being the centre of curvature of $\pi \pi'$)—is equal

Fig. 4.

to the angle $\pi s \pi'$,—s being the corresponding centre for the arc $\pi \pi'$. But if these two angles be equal, it follows that the line or distance $\pi \pi'$ is greater than the line or distance $m m'$, just because πs is greater than $m s$; that is to say, provided the earth be an ellipsoid whose minor axis is the polar, the length of degrees of Latitude—measured geodesically—must increase from Equator to Pole: and the ratio of this increase, depending on the ratio of the axes of the ellipse, will, if accurately determined, reveal that ratio. To measure such arcs in different latitudes has been the object of many great Surveys, undertaken on a scale, whose costliness could be met only by the resources of great Nations. England, France, and Russia have all contributed munificently in aid of the gigantic work; and the mean or average result of all the measures is, that the Ellipticity of the Earth is 1-299th, or that the axes are to each other as 298:299. Corresponding results may be derived from the measurement of degrees of Longitude, at different Latitudes, but the explanation of this method must not detain us here.—It falls to be observed, however, that the various measurements effected, do not quite harmonize; nor is it possible to explain the discrepancies otherwise, than by attributing them to unknown irregularities in the inner structure of our globe,—irregularities which affect the level or the plummet, and must therefore deprive all such researches of the attribute of ultimate accuracy.—(2.) The ellipticity of the Earth is also indicated by that invaluable Physical Instrument, the Pendulum. We shall suppose that the length of the Pendulum vibrating seconds, has been measured at various latitudes, with extreme nicety, and corrected for the influence of the varying density of the air in which it oscillates—a process of no trifling delicacy and difficulty. Now theory tells us that g , or the force of attraction, under which the pendulum oscillates, is determined by the simple formula:—

$$g = \frac{\pi^2 l}{2 t^2}$$

But the force of gravity depends on the shape of

the Earth; or on the distance of the place from the Earth's centre. That distance, then, at Pole, or Equator, or intervening positions, will follow from the length of the second's production. The average of a multitude of observations in this case, gives the ellipticity at 1-285th.—(3.) The remaining method of determination, depends on the relation between the Earth's protuberance, and certain important phenomena in Celestial Mechanics. It is the action of the Moon and Sun on this protuberance, which gives rise to the phenomena of PRECESSION and NUTATION (*q.v.*), and that protuberance reacting on the Moon, produces inequalities in her motions in Longitude and Latitude. It is impossible to evolve the ellipticity from these motions, without an assumption as to the law of the increase of the Earth's density as we approach the centre; but an assumption that cannot be far from the truth, gives 1-805 as the result.—Upon the whole, then, it may be taken as a conclusion worthy of reliance, that the Earth is an elliptical spheroid, rotating around its shorter diameter, and that its ellipticity is about 1-300;—which signifies that the Equatorial diameter is longer than the Polar by about four and a-half times the height of *Mont Blanc*.

(3.) *The Earth, Density of.*—The achievement which most of all astonishes the young student in Astronomy, is probably its accurate determination of the weights of the celestial bodies. It will be explained elsewhere in what manner the weight of every constituent in the solar system can be compared with the weight of the Earth and measured by it: it is our present purpose to explain the methods by which our own globe is weighed, and that weight expressed in *pounds avoirdupois*. We shall notice three methods—all depending on the same principle, viz., a comparison of the attractive force of the Earth with the attractive force of some smaller body whose actual weight we can estimate.—(1.) The first method, known for upwards of a century, consists in observing how much a mountain mass *deflects a plummet from the vertical position*. This deflection, accurately measured, indicates the relative powers of the Mountain and the Earth: so that, if the actual weight of the Mountain could be calculated, that of the Earth might be inferred. Bouguer, long ago, noticed the deflecting or disturbing effect of *Chimborazo*; but it was reserved for Maskelyne to conduct experiments with the express view of carrying out this inquiry. He chose the Scottish mountain *Schehallien*—a large mass, stretching east and west, and alike steep on the north and south. The deflection of the plummet amounted to from 4" to 5": and, assuming a certain density or weight of the mountain, it was easy to infer from such a deflection, that the mean density of the Earth is nearly five times greater than that of water. The chief element of uncertainty is evidently this,—supposing the observations to be

scrupulously accurate, how is it possible to determine unmistakeably the weight of the mass of the mountain? Still Maskelyne's conclusions were entitled to a certain authority; and they undoubtedly constituted the first reliable step in a remarkable inquiry.—(2.) The second method is much more accurate; for although the conduct of it demands an unusual nicety, it does not require us to deal with any indefinite quantity whatsoever. It is the method known as the *Cavendish Experiment*,—performed originally, on the suggestion of Michel, by the well-known Henry Cavendish, and recently repeated by Reich of Freyberg, and Mr. Francis Baily. The general character of the apparatus, as used by Mr. Baily, is represented below.

Fig. 5.

Two balls, A and B, of about two inches in diameter, and carried on a rod AB, are suspended by a wire DE; and their position observed under every precaution, by aid of a telescope. This position determined, large balls of lead, twelve inches in diameter, placed on a turning-frame, are brought near them, in so careful a way, that they could produce no effect on the small ones, *except through the force of their attraction*. On the approach, the small balls moved towards the large ones by a very trifling quantity, and this quantity was carefully measured. By aid of the turning-frame, the position of the large balls is then reversed, and the deviation again noticed. From multiplied experiments, (Mr. Baily made upwards of 2,000,) the amount of deviation or deflection was accurately determined. This element ascertained, the calculation is brief. It is no difficult matter to compute what *dead pull* the large balls must have given the small ones to produce such a deviation. But if lead balls, twelve inches in diameter, exert such a force, what would be their force, or their *dead pull*, were they as large as the Earth? A question easily answered. Now, the attractive force of the Earth is known; that being the

weight of such balls, or their tendency to fall:—the attractive power of the Earth, therefore, may now be compared with the attractive force of lead; and since the density of the latter is known, that of the former must thereby be determined. It turns out, from Mr. Baily's results, that our globe is 5.67 times heavier than an equal volume of water;—a conclusion almost accurately divined by the memorable sagacity of Newton—*“Verisimile est quod copia materię totius in terra, quasi quintuplo vel sextuplo sit quam si tota ex aqua constaret.”* (*Principia*, iii. 10.)—(3.) A third mode of determining the Earth's mean density has recently been put in practice most successfully, as far as the experimental portion of it is concerned, by Mr. Airy, *Astronomer Royal*. It consists in comparing two invariable pendulums, the one on the Earth's surface, and the other at a considerable depth below that surface. The difference of their rates will give the difference of gravity for that depth; and from this the mean density may be computed. The experiments were made at the close of 1854, at the surface, on the banks of the *Tyne*, and at the bottom of a pit of Harton Colliery, one of the deepest coal mines in this country. This low station was no less than 1,260 feet underground. The ready means of communication now afforded by *Electro-Telegraphy*, put it in Mr. Airy's power to render his comparisons perfect; and, as a matter of course, he overlooked no requisite correction. The pendulums differed in rate $2\frac{1}{4}$ seconds per day; from which it follows that the gravity for that depth was increased by the 1-19190th part. The density of the Earth deduced from this result, is between six and seven times that of water; but Mr. Airy thinks that, as yet, he has not taken full account of the *hollow* of the *Tyne*, of the basin named *Jarrow-slake*, of the scoop indicated by the sea, and of the real and observed specific gravity of the rocks covering the mines of Harton. The necessity of bestowing values on considerations like these, shows sufficiently the *weak* part of this mode of determination:—on the whole, we had rather trust to the Cavendish experiment.

(4.) *The Earth, Temperature of*.—The question as to the actual heat of the surface of the Earth—as the momentary equilibrium of various heating forces—falls in the main within the sphere of Meteorology, and will be discussed under one section of article TEMPERATURE. The forces referred to, are the Caloric Action of Space, the Caloric action of the Sun, and the proper Heat of our globe itself: the last only, rightly belonging to the Physics of that globe. That the Earth has a proper or special temperature,—or that large portions of it have so—is evinced by many phenomena, of which the following is the chief: As we descend beneath the surface, *diurnal* variations of temperature grow less and less palpable, and at length they cease. The temperature of this stratum varies only with the seasons.

Descending still further, the variations of the seasons, in their turn, show less and less amplitude, and also practically cease to be indicated: the temperature of this stratum is the average temperature of the year, and may be called the limit of solar effect. Now, below this line or stratum, phenomena occur, in all respects highly remarkable. The temperatures of inferior strata, instead of diminishing, as they recede from the sphere of the influence of the Sun, augment according to a very perceptible rate:—the fact of which augmentation is undoubted, being proved alike by the phenomena of hot springs, and the increase of the temperature of the strata in deep mines. The only point at all in question has reference to the *universality of this increase*. It is certainly still open to doubt, whether the observations have been extensive enough to entitle us to assert that the fact may not affect large, but perhaps peculiar districts alone. The average rate of the observed increase, is that of 1° of Fahrenheit for a descent of between 40 and 50 feet; or of about 100° per mile. At the depth of fifty miles, supposing this rate to continue uniform, a temperature of 5000° would prevail; and as no solid element that we know of, could resist fusion at such a temperature, the inference—granting the accuracy of the premises—would be, that our globe is only a thin solid crust, environing a liquid molten mass. This conception of a *central heat*, has been the favourite one. Fourier takes it as the basis of his remarkable theory; and Humboldt and other geologists of widest view, have discerned in this central Heat, and in the action and reaction between the liquid centre and a thin solid crust, the cause of volcanoes, earthquakes, and our grand secular elevations. With every respect to these illustrious names, we must interpose, that the reference of those superficial convulsions and upheavings—momentous to us, but trifling in regard of the whole Earth—to such a cause, is certainly, the explanation of a small effect by a tremendous premise: but, what is much more important, Mr. Hopkins appears to have definitely shown, that the Astronomical and thoroughly ascertained phenomena of *Precession* (see that article,) are dynamically irreconcilable with any such thickness of crust.—Another solution has been offered recently by Poisson. He imagines that, through some cause, the various regions of space may have different temperatures; and that, as the sun sweeps on, in virtue of his movement of translation, the planetary system will be plunged, now into a cold region, and again into a warm one. If we have left a warm region, and entered a cold one, the body of the Earth must now be cooling, and the increase of temperature to a great depth below, becomes explicable, apart from the hypothesis of a central Heat.—It were needless to go into other hypotheses. The habitations of the Earth, and the entire subject of the sources of Heat, are as yet too little

known, to entitle us to take up dogmatically, any existing positive theory whatever.

Earthquake. The change which, within these few recent years, has passed over our knowledge of this most stupendous and alarming of terrestrial phenomena, happily constrains notice of it, in a dictionary of physical sciences. The ability of Mr. Mallet, of Dublin, alike in his investigation of physical causes, the critical discussion of historic records, and his experimental verification of bold and unlooked-for deductions, appear to have dispelled, in regard to earthquakes, that mystery and misconception with which every subject affecting our wonder and apprehension continues surrounded, until inquiry has revealed its laws. For two reasons, we shall make no attempt to narrate the recorded sights, sounds, and motions that are said to accompany earthquakes:—*first*, because the general impression regarding them is nearly as correct, as such records, in the state in which they are presented to us; and we have no space to follow Mr. Mallet's searching and convincing criticism: *secondly*, because the actual facts will be much better understood from a simple statement of their explanation.—Earthquakes are the consequence of a shock or impulse of some sort inflicted on the solid portion of the earth, at some point below its surface. This shock is sometimes accompanied by permanent elevation or subsidence of portions of the surface: with this effect or concomitant, however, we have nothing at present to do: the earthquake, properly so called, results from the shock alone. Now, this shock may be given right under some continent, or within part of the solid earth lying beneath the ocean. This latter is the more complex case, and also the more usual one: we shall trace, therefore, only its consequences. Such a shock, it is evident, will affect *three* of the constituents of the globe,—*the solid mass* above the seat of the shock—the *ocean* lying over the seat of the shock—and the *superincumbent atmosphere*. Let us attend to these three effects separately.—(1.) A shock, whatever it be, communicated to any point of an elastic solid mass, is propagated by two kinds of *vibration* or waves. In the first place, there is an *elastic wave of compression*, that moves onward on all sides in circles, proceeding from the point of shock as a centre, and carrying to a distance a sense of the trembling, or of the original shock. Such waves of trembling or undulation go in all directions, vertically as well as horizontally—but much farther horizontally than vertically. The state of the neighbourhood when a heavy railway train passes through a *tunnel* illustrates both. On the top of the tunnel there is a vertical movement of the soil, however slight; and at a far greater distance, horizontally, a trembling or agitation is felt. Slightest causes propagate such oscillations:—we have heard that the sudden shutting of the outer gate of Green-

EAB

wich Observatory has sufficed to make a star appear to start out of the field of view of the transit-telescope. It is not possible, then, that the sudden upheaving of a part of the solid earth, and perhaps its immediate and violent fracture, should not propagate waves of compression all around it: and on the solid *surface* these will have the exact appearance of low and broad waves at sea, only rushing on with an extreme velocity. The velocity of their propagation depends, of course, on the elasticity of the earth's surface; but as every part of that rocky crust is highly elastic, when compared with water, the earthquake wave through the solid portion of the earth, will greatly outstrip the primary sea wave in swiftness. The rate of its transit is probably not less than 2,000 feet per second on an average; and it is to this swiftness of propagation, and not to *internal fissures*, &c., that we must attribute such phenomena as the agitation of our Highland lochs by the earthquake of Lisbon. This solid wave, presenting all the forms of a low wave—with such a velocity of propagation—is the cause of the more fearful of the consequences of earthquakes: and Mr. Mallet has abundantly shown, not only that prevalent conceptions regarding *vortical* motions are as unnecessary as untenable, but that every established fact of concussion or demolition may be referred to the action of such a wave. And he has shown further, that inasmuch, as through the varying elasticities of different rocks composing the crust of the earth, this wave cannot be propagated circularly any more than the ocean waves—the deviations from uniformity of propagation will amply explain all established phenomena apparently at variance with this simple physical theory. — A second wave, however, is transmitted through this solid crust, viz., the wave of *sound*. On occasion of a fracture of the strata, from whatever cause, such a wave will instantly be propagated, and with an immense velocity, possibly from 8,000 to 10,000 feet per second. Hence the rumbling noise often preceding the shock of earthquakes.—(2.) The next wave, in physical importance, is the great sea wave. This must be distinguished from the wave or sea agitation, which the solid wave in the bed of the ocean must, as it were, *carry on its back*; and which must always have caused that phenomenon of the recession of the sea, noticed so frequently as coincident with the shock of earthquakes. The primary ocean wave—a large but low one—propagated on all sides, and modified as it proceeds by the depths of the channels over which it flows, must alternately dash on all coasts in the neighbourhood of the primary shock, and produce effects of its own. But as the progress of the solid wave and that of the liquid one is not determined by the same condition,—that of the former, depending on the elasticity of the solid strata; that of the latter

EBU

on the mere depth of its channels,—it cannot but be expected that discrepancies, and even apparent disconnection should arise. A peculiar wave of sound must also be propagated through the ocean lying above the locality of the shock.—(3.) The *third wave*, is produced by the agitation of the *atmosphere*. If the original agitation has been sufficiently abrupt to cause an adequately swift vibration or oscillation in the superincumbent atmosphere, a great wave of sound will be propagated in the usual way. This must be low in note, and must reach the ear considerably after the shock has been experienced.—Such are the causes of the phenomena. Mr. Mallet has not stopped with a mere general appreciation. And important experiments, on a large scale, directed by him, have been recommended by the *British Association*.—See its valuable *Reports*.

Ebullition. The phenomena of ebullition and spontaneous evaporation differ in this material point, that in ebullition the vapour is formed within the mass of the liquid, while in evaporation, it is formed at the exposed surface. In what circumstances can vapour be so formed? Only when it obtains sufficient tension to resist the pressure round it. Vapour will not be formed within the liquid, where the pressure is 15 lbs. per square inch, provided no force is introduced capable of giving that vapour an opposite tension at least equivalent. The force ordinarily employed in producing ebullition is heat. Galvanic currents, and other agencies, also produce it; and they likewise do so by giving sufficient tension to the vapour to enable it to resist the surrounding pressure; that obtained, it is immaterial what way it may come. The boiling point of a liquid depends, indeed, upon the pressure to which the liquid is subjected; and the condition of boiling is very simple—namely, that the heat or other agency be such as to induce a higher tension in the vapour than the pressure can keep down. The consequence of this ought to be that, if we ascend a mountain, on the slopes of which the pressure of the atmosphere is less than at the surface, liquids ought to boil at lower temperatures than at the surface. They actually do so. The following table will illustrate this:—

	Yards high.	Inches of pressure.	Boiling point.
Farm of Antisana,.....	4488	17.87	187.34
Quito,.....	3170	20.74	194.18
Mexico,.....	2490	22.52	198.14
Convent of St. Gothard,....	2302	23.02	199.72
Briançon,.....	1428	25.29	208.9
Baths of Mount Dore,.....	1186	26.28	206.7
Madrid,.....	663	27.72	208.04
Phombières,.....	469	28.29	209.12
Moscow,.....	328	28.82	210.2
Lyons,.....	177	29.33	210.32
Vienna,.....	144	29.41	211.1
Paris,.....	71	29.69	211.46
Sea Level,.....	0	29.92	212

The same law holds with regard to all liquids. But these boil, under the same pressure, at differ-

EBU

out temperatures. We give below the temperature at boiling of several well-known liquids:—

Sulphuric ether,.....	100°04
Sulphuret of carbon,.....	116°8
Alcohol,.....	175°84
Water,.....	212
Essence of turpentine,.....	314°8
Phosphorus,.....	564
Sulphur,.....	570°2
Sulphuric acid,.....	590
Linseed oil,.....	600°8
Mercury,.....	662

It appears, then, that different liquids boil at different temperatures, and that any given liquid under lighter pressures will boil at lower temperatures. The opposite of the latter result will hold good; i.e. bodies boil at higher temperatures under heavier than ordinary pressures. Hence, as in Papin's *DIGESTER*. We can easily conceive of how much importance this is, when one wishes to apply a very regular heat to a body—a desideratum impossible of attainment by ordinary combustion. The proper process is to generate steam of the temperature required—regulating the pressure under which the water is placed, according to the temperature—making a partial vacuum of it, if intended to be low, and forcing in high pressure air, or enclosing it simply in a strong vessel like Papin's *Digester*, with a valve to open at the proper time, if the temperature is to be high. The boiling point also depends somewhat on the nature of the enclosing vessel. Thus in glass, water boils more slowly than in metal pots. The roughness of the surface helps it—just as there is no action on amalgamated zinc, in a battery where rough zinc is powerfully decomposed. Probably there are little galvanic currents excited which assist the formation of the steam. If we throw in a few scraps of metal into a glass pot, the steam forms about as quickly as it does in a metal one, and it first forms on these scraps; or, if we make a scratch with a diamond on the inside of such a vessel, we see the same formation of steam first round it. The boiling point is only, however, very slightly altered by the insertion in a liquid of masses of solid matter, and not at all if the sides of the vessel be rough and the matter be not dissolved. Thus, if we throw sand into a pot of heated water, it will boil neither sooner nor later for that. If, however, we insert some matter which is soluble, we obtain what in reality is a new liquid, and the boiling point does change. It is worthy of note that, if there be a very small aperture permitted to the steam forming from water to escape by, the temperature of the steam varies with the proportion borne by the aperture to the whole vessel. The quantity of vapour emerging in a given time is, generally, very much the same; but there seems to be a decided heating effect in the mere rushing of the steam through the aperture. The issuing steam seems to give back part of its heat to the remaining mass; and the more, the smaller the aperture. Thus—

EBU

Temperature to which the water rises.	Proportion of surfaces of orifice of vessel.
212°.	1-1,000 and upwards.
221°.	1-5,000 „
289°.	1-10,000 „
280°·4	1-20,000 „

A very curious phenomenon, first noticed by Leidenfrost, has been recently investigated with great care by Boutigny. It is this: if a drop of water, or any volatile liquid, be put upon a very hot metal vessel, there will not be, as might have been expected, any immediate vaporization. The globule will, instead of that, float on the metal, as a needle does on a vessel of mercury, without wetting it. The heat, when so violent, produces a repulsive force, which keeps it from touching the metal at all. If the metal gradually cool, there will be a wetting of it, and then an immediate evaporation. The character of the liquid and of the metal go, together, to determine the temperature at which the vaporization takes place. The play of repulsive forces, M. Boutigny informs us, induces the globule always to take an ellipsoidal or spheroidal shape. He mentions 340° as about the lowest temperature at which the result described is produced for water. A drop takes a spheroidal shape—a larger quantity becomes flattened in shape—always retaining the form of an ellipsoid with its axis vertical. A somewhat remarkable result will be obtained, by darting a jet of sulphuric acid upon the watery globule. It adheres to the heated body readier, and is suddenly volatilized by the violent heat. The heat of volatilization comes also however, from the water as well as from the heated body; and there is so much thus abstracted as to freeze the water at the bottom of the red-hot vessel in which it is contained.—A very interesting application of the theory of ebullition may be made in determining by means of it the height of a mountain. Taking Regnault's values of the tension of vapour of water as correct, water which would boil at 90° centigrade, or 194° Fahr., would indicate a tension of 525·45 mill. (20·66 inch) of mercury—the standard being 760, and the weight of the air is diminished exactly in this proportion. If, therefore, at the top of a hill you get water to boil at 194° cent., you have a pressure =

$\frac{525 \cdot 45}{760} \times \text{atmospheric pressure at surface.}$ If now, observations be made, or calculations, which may show us how much the weight of the atmosphere diminishes as we rise, and what is its weight at each point above us, we can, comparing this weight with it, obtain the height of our observed point. The simple rule—perhaps as correct as any that can be given for moderate heights, is that the boiling point is lowered 1 degree for every 550 feet of elevation. Thus water boils at 184° on the summit of Mont Blanc, giving it an elevation, by this rule, of 15,400 feet, while its actual height is 15,780.

ECC

Eccentric. (Ptolemaic Hypotheses.) When the ancient astronomers found that certain of the heavenly bodies, as the Sun, do not move in an exact circle, which, as they fancied, is the perfect figure, or at a uniform rate, they adopted a new hypothesis to save their old one. This was the problem. The sun (*e.g.*) appears to do something, which seems not moving uniformly, or else not in a perfect circle; but as he must move at once uniformly and in such a circle—required the explanation of this false appearance? They supposed that the standpoint from which we view his motion, viz., the earth, is not in the centre of the circle which the sun describes, but nearer the circumference (as

E within P Q A). Now, if the sun do move in a circle, and at a uniform rate, his movement in a given time will be along P G. In the next time of the same length he will describe G F, equal to P G. These lines, P G, G F, will subtend equal angles at the centre C, because equal arcs; and to an observer at E, therefore, who measures their motion by the angular space passed over, they will appear to indicate uniform circular motion. But an observer at E, sees the angles G E P and F E G to be described in equal times, and these two angles manifestly vary in value. Hence the body moving along P G F will appear to describe unequal spaces in equal times, to the spectator at E. This is exactly what the sun does, to the inhabitants of the earth, (in fact, his motion can be very closely approximated to, in this way, by an appropriate choice of the position of E—see ANOMALY); and it follows, therefore—since the postulates already advanced are indisputable, according to the old astronomers—that the earth is in the position E. The circle is called an *eccentric*.

Eccentric (Steam Engine) is a circular plate fixed in the rotating axle of a steam engine, so that it may pass at some not very large distance from its centre. By its means the valve gear and pumps of the engine are wrought very easily. It is an engineering contrivance of Murdoch's, and is almost universally adopted in engines.

ECH

Eccentricity. In such circular motion as the one above described (where there is a uniform motion in a circle, in the centre of which the spectator is not,) the excentricity, or eccentricity, is the ratio which the distance E C bears to the radius. In an ellipse, it is this same ratio—namely, that of the distance between either focus and the point of bisection of the line of foci (the centre of the curve), and the major semi-axis of the curve. In the older works on astronomy the term is also applied to the value of this line itself. (*Technical.*) The mathematical expression for the eccentricity of the ellipse is $\sqrt{\frac{a^2 - b^2}{a^2}}$, and of the hyperbola $\sqrt{\frac{a^2 + b^2}{a^2}}$.

Echo. We have seen (ACOUSTICS) that, in all ordinary cases of sound, there is vibration of the air or other elastic media; and that to this, the impression of sound is due. We have supposed, there, that the sound has been propagated from its source to the ear directly, and that its source was a body in which, by direct action, vibration had been produced. Suppose, however, that such a body sends out a pulse of vibrating air, which strikes upon some one that will not permit its passage. Here we have a mere repetition of such an impact as may produce vibration. The body which has interposed has such motions excited in its surface; and these again send back the air in similar pulses. This phenomenon is called that of the reflexion of sound, and to it is due what is called an echo. When light is reflected, we have seen (CATOPTICS) that the returning ray moves in such a direction that the angles of incidence and of reflexion are equal. The same law holds in sound. In that case, however, we were permitted to consider light as composed of a number of independent rays, which could be reflected also independently, and which, in their course, do not communicate their own vibration necessarily to the luminiferous ether round that section of it through which they pass. But here we must consider that every vibrating point sends out vibrations in all directions round it; and that, when a surface is set to vibrate, the various parts of it originate vibrations which may, to a considerable extent, interfere the one with the other. There is not very much importance to be attached to this effect, however, in the simpler cases, and, in consequence, the same laws may be conceived to hold for sound that have been proved to hold for light. (CATOPTICS.) Thus, if a sound be made at one focus of an ellipsoid, a series of sonorous vibrations will be excited, all of which will be sent back from the ellipsoidal surface, according to the law of reflexion, to the other focus. Hence, if a person stand there, all of them will strike on his ear, and a sound much more violent than could be heard by a person listening to the direct sound at any point of the ellipsoid will be the result. The person standing in the focus will

first hear the direct sound, and then the reflected sound, in one volume. The velocity of the sound wave is the same after as before; so that, as the sum of the lines drawn from the foci to any one point in an ellipse is constant, all the waves reflected from each elliptic section of the surface will converge at one moment—traversing equal spaces in equal times. This species of vault, therefore, will give the most powerful echo. A circular dome will illustrate this also, if we place ourselves at the centre. A circle is just an ellipse where the foci have come to meet in one point. Hence, we will hear the sound which we create, and its reflexion from all the circumferences also. The two sounds in an ordinary dome will appear as if the same. The sonorous wave travels 1,090 feet in one second, so that the abstract difference of time in a dome of $54\frac{1}{2}$ feet in diameter would be about 1-20th of a second only. An echo in this way can be always produced from an elliptic surface, without taking into account the distance of the foci. Any surface may, for a small space, be considered as part of an ellipsoid—one which would just touch it there—and so from any surface we might have an echo. This echo, however, would not be at all the same as that where the whole elliptic surface—catching the whole volume of emitted sound, reflects it on to the other focus. There is only a little portion which sends back the sound accurately to that point, and the echo is, therefore, much more faint. Moreover, the elliptic surface so formed to correspond with the actual surface—i.e. touching it at the specified point—may not have its focus at the origin of sound, and most frequently has not. The echo which we have just considered, is that of sound accurately reflected to the ear. Diverging first from its point of origin, it meets a surface which makes it converge back to a new point, where the ear is situated. But it is not all surfaces that can make sound so converge. Referring back to the case of plane mirrors (CATOPTRICA), we shall find that there is produced, in the reflexions of light, a series of rays which do not at all appear to converge, but appear as if they had come diverging from a point different from that where they actually originated. So it is often with sound. Reflected waves go off from the impinging body in such a direction that they appear as if they had come from a different point. Though this point is behind the mirror, an eye situated behind the mirror would receive no impression of light, because the rays in fact do not pass through; but an eye before it will. Similarly an ear situate before a plane reflecting surface, will catch reflected sound, and be impressed with it as if it came from a point behind the surface. The ear may blend the two sounds together—if the distance from the surface be not great; or if great, there will be a distinct echo, as if from a place farther away. When we see a body and its reflexion in a mirror at once, it is impossible, from the velocity of light, for us

in any case to distinguish between the time of the impressions. Hence the ear, not trained nearly so well as the eye to discover distances from impressions upon it, will confuse the two sounds, if they do not come at intervals quite distinctly perceptible. If, however, our distance from the sounding body and the point where a body seems to have been sounded, in consequence of the reflexion, be any considerable portion of 1,090 feet, there will be a perceptible interval elapsing between the two sensations, and we will distinguish a decided enough echo. If, as is very usual in echoes, or rather, as is most usual in those which have been observed, we hear the returning sound at the same place where the sound is made—when we speak, for example, and are answered by an echo—there must exist a reflecting surface perpendicular to a line drawn to it from our position; only that wave of sound which goes from us, perpendicular to the reflecting body, can be sent back to us accurately. We found, in the article on CATOPTRICA, that this property of causing divergence of luminous rays was not confined to plane mirrors, but exists also in convex ones of all sorts. The same property holds with regard to convex reflections of sound. There, however, as in the mirror, the focus from which the reflected wave (of light or sound) seems to come is, generally, nearer the centre of emission of the sound than is the case of the plane mirror. There is an echo, therefore; but the tendency to confuse the echo with the original sound becomes more decided; so much so, indeed, that it may become almost as if the point of emission were at the reflecting surface itself. Hence, these echoes are not so readily noticed as in the case of plane reflection. Very often, as we have seen, concave reflectors make the sound actually curve back before their surfaces, so as to pass through a point at which the auditor may be placed. In plane reflectors, it seems always to pass from a point behind. We may imagine, therefore, reflectors of different concavities which may permit the rays to appear divergent, as if they came from a point behind. We may, therefore, have also with concave reflectors what might be called the *virtual* echo, in which the reflected sound appears to come from a point through which no sound actually passes, just as the reflected image appeared to do so. We have spoken of the distance between the point of emission—the point of reflexion—and that of hearing, as being those upon which depends the confusion of echo with, or its distinct separation from, the original sound. Where the image of the sound is actually made at the point at which we hear it, the sum of the distances of the points of emission and of hearing from that of reflexion, respectively, must be a moderate fraction of 1,090 feet, for any sound to give a distinct echo. Where, again, the image is *virtual*, the difference of the two distances of the points of emission, actual and virtual, from the ear must be such a fraction. If the dis-

tance of the auditor from the actual point of emission were greater than from the virtual point, we should hear the echo sooner than the original sound, but a recurrence to the figure for plane mirrors (CATOPTICS) will readily show that this is impossible. In fact, the distance from the point of virtual emission to the ear is equal to the sum of the distances of the point of reflexion from that of actual emission, and from the ear. These two last lines, along with the distance of the ear from the point of actual emission, form a triangle, and their sum is, therefore (I. 20), greater than that line. Hence the echo can never come before the sound to be echoed.—It is usual to describe an echo by the number of syllables it repeats. This depends on these distances, in the same way. We can repeat so many syllables in a certain time. Hence, if an echo takes up our repetition of 15 syllables, after we have just finished it, there is a sort of measure furnished of the distances referred to. Some of them are quite measurable—and we can, therefore, sometimes calculate the position, in a simple echo, of the reflecting body. Sometimes, however, we have a more complicated case to deal with. The reflected wave may be again reflected, and that again and again and again before reaching us. If the position of these reflecting bodies is quite unknown, it will not be easy to find it out. When the centre of emission of the sound moves during the time that it is sounding—if it move with a greater velocity than that of sound, the position relative to us may manifestly be so much altered that we shall hear the latest emitted sound first, by reflection, and the first latest. Thus a flash of lightning moving towards us produces a sound which is echoed by the clouds; and, as its velocity is so much greater than that of sound, we shall hear the reflexion of the last emitted sound, first—and, as we distinguish distances to a slight extent by the ear, calculating from the intervals of sight and sound, we shall seem to hear the thunder roll backward when the lightning has been moving forward. The clouds are capable of reflecting sound as well as more solid bodies, although the reflexion is not at all so distinct. Some bodies of much more substantial texture absorb all vibrations more completely. Thus carpetings and cloths are nearly effectual cures, if applied properly, for the most violent echoes. The sail of a ship at sea, when distended by the wind, is like a stretched string, very sensitive to impressed force, and evidences this very readily by sonorous vibrations. The particles of the atmosphere play a very important part in the reflexion of sounds from their own mass—not merely transmitting them passively; just as the same particles reflect light and give rise to the phenomena of dawn and twilight. They do not reflect at all so powerfully, however, as clouds do. Thus a cannon fired on a clear day and on a cloudy day, will give a perceptibly different report with the same charge. A cir-

cumstance frequently noticed in the case of echoes, is that, after ceasing, they appear to begin again. Sometimes this arises from the fact, that the reflected sound has passed through one portion and struck on another surface perpendicular to its direction, or on a series of surfaces from which it has been again reflected back. As in no case is there not some loss of sound in producing these internal vibrations; and as, generally speaking, smaller and smaller fragments of the original sound wave are reflected every time, the second echo will be fainter than the first, and, if reflected again, fainter still. Sometimes it arises from another cause—namely, that there are, in fact, two reflecting surfaces, at different places, from which the original sound is reflected. The one, perhaps, 500 feet distant, gives an echo in about half a second; while another, perhaps, 2,000 feet distant, gives another echo in about two seconds. The effects of echoes on buildings in rendering them unfit for particular purposes, will be described in the article HEARING.

Eclipses. It happens occasionally that the sun's disc loses its usual circular form. It becomes indented on one side, the indentation increasing gradually in extent; then gradually diminishing, until finally it disappears. Sometimes this indentation augments until the whole disc is covered, and the sun remains for some minutes out of sight. At the end of that time he reappears, passing successively in the inverse order through the same phases that had preceded his disappearance.—The moon, also, from time to time, undergoes similar modifications in the form of her disc, which must not, although there is a certain resemblance, be confounded with her phases. They last never longer than some fraction of a day; they are much more irregular in their reappearances, and these are separated by much larger intervals.—These remarkable phenomena, which were objects of terror for a long period, exciting, however, only our curiosity now, are called ECLIPSES. Those of the sun happen always at the time of the new moon, and those of the moon always at full moon. This indicates the explanation very readily. At new moon, the moon, which is passing between the sun and the earth, may hide a larger or smaller portion of the sun from us; and there is an eclipse of the sun. At full moon, the earth is between the sun and the moon, and may therefore keep the sun's rays from falling on her surface, so that it becomes a dark body—and there is an eclipse of the moon.—If the moon kept, in its motion round the earth, constantly in the plane of the ecliptic, there would manifestly be an eclipse of the sun at every new moon, and one of the moon at every full moon. They do not happen so often, because the moon moves in a plane inclined to the ecliptic; so that being sometimes on one, and sometimes on the other side of it, and at various distances from it, it passes at the

moment of syzygy far enough from the ecliptic to prevent there being an eclipse. There can only be an eclipse at those times of new or full moon, when the moon is in the point of her orbit where it cuts the ecliptic, or near that. From this circumstance the name *Ecliptic* itself comes. We shall enter into some explanations of the circumstances which accompany eclipses of the Sun and Moon, and the methods employed for predicting their return. We shall begin with—

(1.) *Eclipses of the Moon.*—Let us try, if we can discover whether it is possible for the earth, coming between the sun and moon, to prevent the sun's rays from falling on her. The sun emits rays of light in all directions. Those directed towards the earth are stopped by it, and beyond it, therefore, there is a portion of space in shadow. Let us conceive a cone, AOA' ,

Fig. 1.

completely enveloping the sun A , and the earth T , touching their surfaces all round. It is easy to see that no solar ray, supposing it constantly to keep its rectilinear direction, will penetrate into that part of the cone between its apex and the earth; whilst it will be seen that there may always be rays, if not from the whole, at all events, from a part of the same body, reaching any other point in space. The part NOB' , then, constitutes the shadow of the earth, turned away from the sun.—That there may be an eclipse of the moon, that body must enter the cone of the shadow. If we draw through T the line TC , parallel to OA , we shall have two similar triangles ONT , TCB , which will give the proportion $\frac{OT}{TB} = \frac{TC}{CB}$.—Taking TC , the radius of the

earth, as unity, TC ($= OA - TB$) will be 111; and the distance (mean) TA , of the sun from the earth is about 24,000. Hence OT will be 216, that is, the distance between the centre of the earth and the apex of the cone will be 216 semi-diameters of the earth. The moon's average distance is only 60 such semi-diameters. It follows that the moon can enter the sun's shadow, and not only so, but, where it enters, the diameter of the circular section of the cone will be very much larger than that of its disc, so that it may be completely within the cone. For, any section nearer T than half the distance OT (108), will be greater than half the size of the earth's disc—that corresponding to the lunar distance from O , giving a space of $\frac{1}{4}\frac{1}{2}$ of this disc, which is much larger than that of the moon.—When the moon only enters the cone in part, the eclipse is said to be *partial*; when it does so completely, it is *total*.—If we conceive

the moon to progress pretty uniformly, and in a direction almost perpendicular to the axis of the cone of shadow, we may get an idea of the leading circumstances of an eclipse. Where it is partial, the shadow gradually increases over the moon's surface till the moon's centre is in that part of her orbit nearest the axis of the cone, and then gradually diminishes and disappears. Fig. 2 will give an idea of the indentation apparent on the moon's surface when the earth's shadow passes in this way over any part of it. The indented rim $a b c$, is a portion of the outline of a transverse section of the cone where the moon is; and the rounded form of the rim, which

is always distinctly noticeable in an eclipse, clearly demonstrates the round shape of the earth, (see *Earth*, Figure of,) which gives character to the cone.—In a total eclipse, the cutting of portions of the luminous disc proceeds till all is so taken away. After some time the moon reappears on the other side of the umbra, and goes through the same phases, identically as before, but in inverse order.—The indentation, when the body is but partially eclipsed, is far from being so distinctly marked as the figure would lead us to suppose. The shadow has a *penumbra*, as always happens when we speak of a shadow cast by an object exposed to the sun's rays.—Let us imagine—that we may have an idea of the size of this penumbra—another cone AOA' , having its apex O ,

Fig. 2.

between the sun and earth, enveloping the sun A , and the earth T , in its two opposite halves AOA' , NOB' , which touch the surfaces of these bodies all round.—It is clear that every point within the space $ONB'C'$, and without the shadow NOB' , must receive rays of light from a portion of the sun's disc only—from such a point, only a portion of the sun could be seen, the rest being concealed by the earth's interposition. It will be clear, too, that the portion of sun seen, or that sends rays to the point, will be greater, the nearer the point is to the outer edge of this space. So that, whilst the moon is moving so as to enter the cone of the earth's shadow, a portion of its surface begins to lose its brightness as it enters $ONB'C'$ —the light diminishing as it goes farther from the outer surface of this space, till it disappears in the

ECL

umbra itself; the different portions of the disc occupying, at different moments, positions within this space corresponding to the penumbra, there must be an insensible diminution of light, from the points illuminated by the whole surface of the sun to those to which no ray reaches. But it is easily seen, that the diameter of the moon's disc is not so large that we should clearly distinguish the penumbra in its whole extent. The angular breadth of the penumbra is exactly the angle COB , and that is equal to ABA' , which is just the apparent diameter of the sun, seen from the earth; and as the apparent diameter of the moon is almost the same as that of the sun, it follows that she may fall almost the whole breadth of the penumbra.—The passage from the pure umbra to the penumbra is quite insensible; the softening down of the shading is so gradual, that it is impossible to tell the exact moment when any remarkable point on the moon's surface leaves the penumbra to pass into the umbra, or the reverse.—There are other circumstances, due to the presence of the earth's atmosphere, which we shall now consider.—We have conceived hitherto the rays of the sun passing near the earth to preserve the rectilinear direction with which they are emitted from the sun. But we know that rays traversing the atmosphere do not maintain their original direction; they change it whenever they pass from one layer to another of different density, when, after entering the atmosphere on one side they leave it on the other, they must have experienced some similar deflexion. Imagine a special ray SA ,

Fig. 4.

passing through the atmosphere near the surface of the sun. The direction of this ray at the point A , where it has become, so to speak, a tangent to the surface, is not the same as it had before passing into the atmosphere; the deviation that it has experienced up to the point A , is more than 38° , in average circumstances. From A , till it leaves the atmosphere, it experiences another deviation equal to that, and in the same direction; so that the line which it ultimately follows makes an angle of more than one degree with the primitive direction. This total deviation of a light ray, in passing through the atmosphere, is the smaller, the farther the ray is from the surface at its lowest point, and may take any magnitude inferior to that just given. We see, then, that the cone of the umbra will not be deprived of sun rays, through its whole extent. They are deflected, so as to approach nearer to the axis. If we consider those rays

ECL

which, like AB , $A'B'$, pass through the lowest strata of the atmosphere, and continue their

Fig. 5.

course, we shall see that they converge at a point D , much nearer the earth than O is. The cone BDB' , which is formed by these rays, divides BOB' into two parts—in the inner of which there is absolutely no light—while the outer, $BOB'D$, receives the light refracted through the atmosphere of the earth. If we find the distance of D from the earth's centre, we obtain for it 42 radii of the earth. We see, then, that the moon (at 60 radii distance) can never enter the space BDB' , which is completely dark—the moon, at the time of total eclipse, is within the partially illuminated space $BOB'D$. That is the reason why she never loses her light entirely, even in such an eclipse.—It will be noticed that this faint light, which the moon retains in total eclipses, is of a very distinct reddish colour. Some bright points, which Herschel had remarked on certain parts of the surface of the body, during eclipses, had induced him even to fancy that there were volcanoes existing in a state of activity; but the whole effect is due to the influence on the transmitted light of the beds of air through which it has passed. Air stops a certain portion of light passing through it, and reflects it in every direction, occasioning a diffused light; but this action is not the same on the different rays of which white light is made up. Those at the violet end of the spectrum are stopped in much greater numbers than those at the red end; which occasions the blue of the sky, the rays of the first kind predominating in diffused light: it also produces the ruddy colour of the illumined clouds at sunset, because the light which reaches them having traversed a great thickness of the atmosphere, contains a larger proportion of the rays of the second kind than white light does. We see, then, that the light which reaches the moon's surface, during her total eclipses, must have a reddish tint, since it does not reach her till after passing through a very great thickness of atmosphere. This red light, when strongly reflected by some peaks of the mountains of the moon, probably occasions the bright points which Herschel took for volcanoes in activity.

(2.) *Prediction of Lunar Eclipses.*—As these eclipses are due solely to the positions of the sun and moon in regard to one another, the knowledge of the laws of the motions of these two bodies must enable us to predict, not merely the periods at which these phenomena must take place, but the various circumstances characterizing them. We shall show how this aim may be attained. The ancients did not know

ECL

the laws of the solar and lunar motions with anything like accuracy; but, by assistance of the period of 18 years and 11 days, which we have mentioned (see CYCLES), they managed to foretell lunar eclipses with tolerable correctness. We know that, if the moon remained in the plane of the ecliptic, there would be an eclipse at every full moon. The reason that lunar eclipses are much less frequent, is simply this, that the moon, if on one side of the ecliptic or the other, when in opposition to the sun, may pass above or beneath the cone of the earth's shadow, without entering it at all: there is an eclipse only when, at the time of opposition, the moon is near enough the ecliptic, or, what is the same thing, near enough one of the nodes of her orbit. If, at two different periods, the moon, being then in opposition to the sun, be also in the same position as regards her nodes, there cannot be an eclipse at one such period unless there be one also at the other. Now, if starting from any observed eclipse, we count on, for 223 lunations, we find ourselves almost at a full moon, where the body occupies the same place with respect to her nodes as at the beginning of that time: since, during it, there have been 19 synodical revolutions of the nodes, we may then, after these 223 lunations, expect a recurrence of eclipses similar to that which went before. We see, in this way, how it was sufficient to have noticed the dates and principal phases of the lunar eclipses for the space of 223 successive lunations, to enable us to predict the return of those eclipses for an indefinite space of time.—If 223 lunations exactly closed the 19 synodical revolutions of the nodes, there would be no necessity for the use of any other methods for the calculation of lunar eclipses. But the equality of the two periods which is assumed,—is merely approximate. So that, if we may certainly foretell, by the help of this period, that an eclipse will happen at such and such an epoch, we cannot very distinctly indicate its time of duration or its character; as it differs in reality a little from the one before, with which, were the period exact, it would have been identical. It might even happen that a very partial eclipse should not reproduce itself at all at the end of 18 years and 11 days; or that a partial eclipse might come, in 18 years and 11 days, when nothing of the sort had been observed before. The use of this period, therefore—the single means employed by the ancients for the calculation of eclipses—is not satisfactory, now that astronomical theories admit of an exactitude so incomparably greater. The laws of the movements of the stars, as science has exhibited them up to this date, have been exhibited by astronomers in tables, by means of which it is possible to indicate beforehand the position which a star must occupy in the sky at any given time. It is on the data, supplied by the solar and lunar tables, that we

ECL

found, in making predictions of the lunar eclipses. But these data are to be obtained elsewhere than in such tables themselves. The *Nautical Almanac* is published by order of the Admiralty, several years in advance; and contains all the indications relative to the positions of the sun and moon in the sky, for every day; and it is by means of these that we obtain whatever is needful for the determination of the different circumstances of eclipses.—To understand the process of calculation for an eclipse of the moon, we must conceive that the radius of the celestial sphere has been selected so that its surface passes through the centre of the moon; this sphere, the centre of which must be supposed placed at the centre of the earth, will cut the moon, with a circular section, and the cone of the umbra of the earth with another; and, by studying the relative positions of these two circles, we come to understand the whole circumstances of lunar eclipses. The centre of the circle of the umbra is always diametrically opposite to the centre of the sun; and so, always on the ecliptic, changing its position, with the same velocity as the centre of the sun himself does, but in the opposite direction. The circular section of the moon, again, also moves, so that its centre remains always on the moveable orbit already mentioned. As long as these two circles remain entirely beyond one another, there is no eclipse; when they cut there is an eclipse; total, if the circle of the moon be entirely within that of the umbra.—In order to compare the successive relative positions of these circles, we must know their magnitudes.—We already know that the moon's diameter (average) is $81' 25'' \cdot 7$, its value for any day in the year, which varies always between $29' 22''$ and $33' 28''$, is given by the *Almanac*, at mid-day and midnight, and we may, by means of these, correct it for any given hour. As for the circle of the umbra, it is easy to see how we may calculate its magnitude. Let mn be the surface

Fig. 6.

of the celestial sphere which we suppose passing through the moon's centre; this surface cuts the cone of the earth's umbra, in the circle mn , and the angle mrt is the apparent diameter, which we desire to determine. Its half, mro , is equal to $bm t$, which is the moon's parallax (since mt is the moon's distance from the earth), less by the angle mor ; but the angle mor , is itself equal to ats (semi-diameter of the sun), less by bat (the sun's parallax); in order, then, to have the apparent semi-diameter of the circle of the umbra mn , we must add the sun's parallax and the moon's parallax together, and subtract the sun's

ECL

apparent semi-diameter. This circle of the diameter is found thus to vary in diameter between $1^{\circ} 15' 32''$ and $1^{\circ} 31' 36''$; its value, at any time, may be found by means of the *Nautical Almanac*, which furnishes these supplementary data. We add, however, that in consequence of the presence of the atmosphere, the earth's umbra appears to have a diameter a little larger than that thus obtained. Mayer has found that, in order to make the predictions of eclipses agree with our observations, we must suppose the diameter of the umbra increased by a sixtieth of its value, and astronomers usually conform to this rule.

Fig. 7.

Let AB be the great circle of the ecliptic, and CD be the orbit of the moon, N will be one of the nodes of this orbit. The umbra O , moves along the first circle with the same speed as the sun moves, and the moon L , along the second with a velocity 13 times as great. In order that—in this common movement—the moon L may meet the umbra O , it is necessary that, at the moment of the moon's opposition, the centre of the umbra be sufficiently near the node N . Remembering that the apparent diameter of the moon and the umbra vary from time to time, and that the distance of the centre of the umbra from the node N is exactly equal to the distance of the sun's centre from the moon's other node, we find that, 1st, if, at the epoch of a full moon, the distance of the sun's centre from the nearest node be greater than $12^{\circ} 8'$, there cannot be an eclipse; 2d, if, at such a time, the distance of the sun's centre from one of the nodes be smaller than $9^{\circ} 31'$, there will certainly be an eclipse; 3d, lastly, if the distance of the sun from one of the nodes be between these two values, the eclipse is doubtful, and a detailed calculation of the circumstances will be required to determine whether it takes place or not.—Let us see now, how the calculation of the different circumstances of an eclipse, and of the precise periods at which its phases will appear, is actually made. The best thing we can do, in that way, is to give an example of this sort of calculation.—Take the eclipse of 13th and 14th November, 1845, at Paris. According to the *French Nautical Almanac* (the *Connaissance des Temps*), on the 13th November, at noon (Paris time), the sun's longitude exceeds the moon's by $186^{\circ} 20' 7'' \cdot 1$; on the 14th, also, at mean noon, the sun's longitude is greater than the moon's only by $174^{\circ} 45' 8'' \cdot 6$. In the interval there must have been a time at which the difference of the two was exactly 180° ; and it is readily found that this moment, at which the moon is in opposition, is on the 14th November, at 1h. 4m. 20s. 9

ECL

in the morning. The *Almanac* tells us that at that time the sun's longitude exceeds that of one of the moon's nodes by about $5\frac{1}{2}$ degrees. We are certain, then, that the moon will penetrate into the umbra of the earth, that is, that there will be an eclipse. We find also in the *Almanac* that, at the moment of opposition,

The Moon's parallax is about....	$55^{\circ} 39'' \cdot 3$
The Sun's parallax is about	$8'' \cdot 7$
The apparent semi-diameter of the Moon's about	$16^{\circ} 10'' \cdot 1$
The apparent semi-diameter of the Sun	$16^{\circ} 12'' \cdot 8$

We infer from this that the semi-diameter of the umbra is about $89^{\circ} 36'$, or $2876''$, so that, increasing it by one-sixtieth of its value, for the reason above indicated, it becomes equal to $2415'' \cdot 6$.—We find again, by the *Almanac*, that, 1st, on the 14th November, at 0h. 30m. in the morning, the excess of the sun's longitude over the moon is about $180^{\circ} 16' 38'' \cdot 7$, and the moon's latitude is about $0^{\circ} 25' 57'' \cdot 6$ Δ ; 2d, the same day, at 1h. 30m. in the morning, the excess of the sun's longitude over the moon's is about $179^{\circ} 47' 37'' \cdot 7$, and the moon's latitude about $0^{\circ} 28' 51'' \cdot 5$ Δ .—By help of all these data we may study the whole circumstances of the eclipse in the following way. Consider the portion of the celestial sphere on which the moon and the earth's shadow are found, during the whole duration of the eclipse, as a plane—a hypothesis which may be made without appreciable error. Suppose, besides, that the earth's shadow is immovable, and that the moon does not move, except in virtue of the movement which it has relatively to this shadow. We may represent the shadow of the earth by the circle $ABCD$ (in the next figure), by choosing the radius OA of this

Fig. 8.

circle, so that it may correspond to the value of the semi-diameter of the shadow ($2415'' \cdot 6$) after the scale which we have adopted in the figure. The straight line EE' , passing through the centre O , of this circle will represent a portion of the ecliptic. At 0h. 30m. in the morning, the sun's longitude exceeds that of the moon by $180^{\circ} 16' 38'' \cdot 7$; the longitude of the centre O , of the

ECL

shadow, exceeds that of the moon's by $16' 33''\cdot 7$, or $998''\cdot 71$. If we suppose longitudes to be reckoned from right to left in the figure, and take OR equal to $998''\cdot 7$, according to the scale—the point R will be the foot of the centre of the moon's latitude for the moment. Raise at R , a perpendicular on the ecliptic EE' , then take on this perpendicular a length RG equal to $25' 57''\cdot 6$, or $1557''\cdot 6$, which is the corresponding latitude of the moon, and we have at G the position of the moon's centre at 0h. 30m. in the morning.—Take similarly OH equal to $12' 22''\cdot 8$, or $742''\cdot 8$, which is the excess of the moon's longitude over that of O , the centre of the shadow, at 1h. 30m. in the morning; then, on the perpendicular to the ecliptic drawn through the point H , take a length HK equal to the corresponding latitude of the moon, whose value is about $28' 51''\cdot 5$, or $1731''\cdot 5$, the point K will be the position of the moon's centre at 1h. 30m. in the morning. We may, without sensible error, consider the movement of the moon, in relation to the shadow, as rectilinear and uniform, during the whole duration of the eclipse. So that, if we draw a straight line MM' through the points G , K , this line will be the path over which the centre of the moon moves, in relation to the circle of the umbra $ABCD$. The point N where the line MM' is met by the perpendicular to the ecliptic drawn through the point O , is nothing else but the position which the moon takes at the moment of opposition, that is, on the 14th Nov., at 1h. 4m. 20s. 9 in the morning.—Describe a circumference from O as centre, and with a radius equal to the sum of the radii of the moon and of the umbra, that is equal to $3325''\cdot 7$; this circumference will cut MM' , the relative orbit of the moon's centre, in two points L , L' . It is very evident, according to the way in which these two points have been obtained, that if a circle be described from either of them as centre with the radius of the moon, which is $910''\cdot 1$, as radius, these two circles will touch the centre of the circle of the shadow $ABCD$, and will represent, consequently, the two positions of the moon relative to the beginning or ending of the eclipse. If, further we drop from O , a perpendicular on MM' , the foot, P of this perpendicular will be the position of the moon's centre at the middle of the eclipse. The moon takes an hour in passing from G to K . According to the proportion between the two lines NP and PK , the length of which may be measured on the figure, we find that the moon should take 5m. 40s. 8 to pass over the distance NP ; it is then 5m. 40s. 8 before the opposition, that is at 0h. 58m. 40s. 1 in the morning, when the middle of the eclipse takes place. Similarly we find that the moon should take 1h. 39m. 19s. 4 to pass over either of the two distances LP or PL' ; it will, therefore, be at 1h. 19m. 20s. 7 on the evening of the 13th November, that the eclipse will begin; and on the 14th, at 2h. 37m. 59s. 5 in the morning, that it will conclude.—Describing a circle

ECL

from the point P , as centre, with the moon's radius, as radius, we immediately see whether the eclipse is total or partial. Here we see it to be partial, because at the moment when the moon's centre is nearest the centre of the shadow, a part of its disc remains outside of the circle of the shadow. If we draw the diameter, QS , towards the point O , and take the proportion between the portion RS of this diameter, which is in the umbra, and the diameter itself, this proportion is what is called *the magnitude of the eclipse*. In the particular case above, the magnitude is 0.92. It is usually expressed in *digits*. We conceive the diameter QS to be divided into 12 equal parts or digits, and state how many of these RS contains. The fraction 0.92, being almost equal to $\frac{11}{12}$, we say that the magnitude of the eclipse of the 13th and 14th November, 1845, is 11 digits. If the diameter QS , were entirely within the circle of the shadow, in which case the eclipse would be total, we should determine the beginning and end of the total eclipse by seeking the positions of the moon, at which its disc, is a tangent interiorly, to the circle of the shadow. This will be as easy as the search after L , L' , where the disc of the moon and the umbral circle touch externally.—Throughout the foregoing, we have been supposing that it was graphically, by measuring certain lengths, on the figure, that the determination of the different circumstances of the eclipse is effected. It will be readily understood that corresponding processes of calculation may take the place of those rather inexact methods, and that thus a much higher accuracy may be attained. This is what is actually done.—To complete our sketch of all that relates to the particular eclipse selected, it only remains to indicate at what places of the earth this eclipse would be visible. Let us seek, in the first place, for all the places where the eclipse may be seen, at the moment of its maximum intensity. We have found that the middle of the eclipse happens on the 14th November, at 0h. 58m. 40s. of mean Paris time. Taking the equation of time, which, at this date (*Almanac*), is 15m. 27s., we see that it is at 1h. 14m. 7s. of true time that this occurs. Consider the point of the earth for which the moon is at that moment at the zenith, it will be readily recognized that it is midnight there, and that, consequently, its longitude west of the meridian of Paris is $18^\circ 31' 45''$. As for the latitude at this point, it is equal to the declination of the moon's centre, at the same instant—a declination which, according to the *Almanac*, is $17^\circ 42' 17''$ N. Hence, we have merely to conceive the earth to be divided into two hemispheres, by a plane drawn perpendicular to the radius which ends at the point whose longitude is $18^\circ 31' 45''$ O, and whose latitude is $17^\circ 42' 17''$ N; the middle of the eclipse will be visible for all the points of the earth situate in one of these hemispheres, and invisible for all of them which are situate in the other.

ECL

What we have just done as to the middle of the eclipse, might be repeated for its beginning and its end; and we should thus find all the places whence it would be seen, either wholly or partially. It is easy to infer that the places from which an eclipse may be seen for the whole or a part of its duration, extend over more than half of the globe.—In order that we may see a lunar eclipse, the moon must be above the horizon, as well as the earth's shadow, or at least a part of it, and this can only take place when the sun is below the horizon; it is only during the night, therefore, that eclipses of the moon can be seen. There are certain circumstances, however, in which we may see an eclipse of the moon for a few seconds before sunset or after sunrise. If, for instance, we stand at such a point as *A* at the moment

Fig. 9.

when an eclipse begins, the whole sun will be below the horizon, and the part of the moon which is found in the cone of the shadow will be equally so; but atmospherical refraction, elevating the bodies above the horizon, will permit us to see the sun and the eclipsed part of the moon at once.

(8.) *Eclipses of the Sun.*—We have said that eclipses of the sun are due to the interposition of the moon between the sun and the earth. It is evident that, when this circumstance occurs, the moon must cut away from sight a greater or less portion of the sun. Let us first attempt to see whether the moon can at any time completely cover the sun?—Following a course completely similar to what we have pursued in the case of lunar eclipses, we may find the length of the cone of the shadow which the moon projects from the side opposed to the sun. Compare this length *OL*, then, calculated when the moon, *L*, is exactly between the sun *S*, and the earth *T*, with

Fig. 10.

the distance *LT*, between the centre of the earth and that of the moon. The radius of the earth being taken as unity, the smallest value of the distance *LT* is equal to 55.947; besides, the greatest value of the distance *OL*, of the summit of the cone of the umbra from the centre of the moon is 59.78; therefore, in the circumstances to which those values of *LT* and *OL* correspond, the umbra of the moon extends to the earth and beyond it. For every point that is completely included within the portion *AB* of

ECL

the earth's surface, the moon entirely covers the sun; there is, then, a *total eclipse*. But, again,

Fig. 11.

the smallest value of the length *OL*, of the cone of the moon's umbra is found to be 57.76; and the greatest distance of the moon's centre from that of the earth is 68.820; when we have these circumstances, the cone of the moon's umbra does not extend to the earth. In this

Fig. 12.

case, there is no total eclipse for any point of the earth's surface; from all points of the hemisphere from which the sun can be seen, a portion, if not the whole of his disc will be seen. One thing is worthy of note, viz., if the cone of the moon's umbra be prolonged out beyond its apex, *O* (last fig.), the second cone will intercept within it a small portion, *cd*, of the earth's surface, over all of which there will be an *annular eclipse*; from every point of it the moon will appear projected as a black disc on the middle of the sun's disc, and the portion of it which stands out, will form a luminous ring all round this black circle. Thus, when the moon places itself between the earth and the sun, there will be a total or annular eclipse, for certain points on the earth's surface, according as their distances from the earth vary.—Other considerations would lead us to the same conclusions. If, at the moment when the moon is passing before the sun, her apparent diameter is greater than his, she will be able to cover him altogether, and there will be a total eclipse:

but, it is easy to see that this may take place, since the greatest value of the moon's apparent diameter from the surface of the earth is 34'.6", and the smallest value of the sun's apparent diameter only 31'.81". If, again, the sun's apparent diameter be the greater, the moon cannot cover his whole disc, so that there will be an annular eclipse; which again may occur, seeing that the least apparent diameter of the moon is 29'.22", and the greatest of the sun is 32'.85"-6. In the latter case, at the point where the centres of the two bodies seem just to coin-

Fig. 13.

ECL

side, the sun's disc will appear as in the figure. At the same time when the eclipse is total or annular at some points of the earth, it will be partial at a great many other points. Conceive, round the sun and the moon, a cone like that which we have used to find the penumbra in lunar eclipses. It will be easily seen that for every point of the earth within this cone $C O' C'$ (fig. 10), not included within the cone of the

Fig. 14.

umbra $B O B'$ or its prolongation, there should be a partial eclipse of the sun; from such a point, we should see the moon project itself on a portion of the sun's disc, producing a circular indentation (fig. 14), and the part covered by the moon should be greater the farther the point of observation is from the surface of the cone $C O' C'$ and the nearer to $B O B'$ (fig. 10). The transversal dimensions of $C O' C'$, in the neighbourhood of the earth are not so great that the globe of the earth can be entirely contained within it. To understand this, simply notice, that because of the littleness of the moon in proportion to the sun, which makes the distances $O L$, $O' L$ appear very small in proportion to the distance $L A$, and sensibly equal, one to the other, the angles $B O B'$, $B O' B'$, are almost of the same size. Notice besides, that the mean length $O L$ of the cone of the moon's shadow being almost equal to $L T$, the moon's distance from the earth, the angle $B O B'$ is not very much different from the apparent diameter of the moon, so that we may consider $B O' B'$ as equal to it. Now, since $O' T$ is sensibly double of $O' L$, the transversal dimensions of the cone $C O' C'$, near the earth T , should be double what they are near the moon L ; the earth's diameter would have then to be only double of that of the moon, in order that the globe should be contained within the cone $C O' C'$, wrapping it round its whole outline. Now we see that it is nearly four times as large as it, so that this cone can include only a portion of the hemisphere of the earth. Hence, when there is an eclipse of the sun at some places, there are others where there is none, but where the whole disc can be seen with no appearance of eclipse.—The moon moves through the sky, about 30 times as rapidly as the sun. Hence, she alternately approaches and recedes from him, and at certain times passes before his disc so as to produce eclipses. Reflecting on this, we readily find the various phenomena which should distinguish an eclipse, to an observer on the earth. They are perfectly analogous to those in the case of lunar eclipses. The eclipse begins when the moon's disc just touches that of

ECL

the sun's. Then the moon slowly encroaches. If her centre does not pass so near the sun's centre, that the distance of the two points becomes less than the difference of the apparent radii, the eclipse will be partial. When that distance is the least possible, the eclipse is deepest. Then the moon moving on, leaves more and more of the sun's surface uncovered; at length the two discs are just separating and the eclipse ends. If the distance of the two centres diminishes below the limit indicated, the eclipse will be total or annular; total, if the moon's apparent diameter, seen from the place where it is observed, be greater than the sun's; annular, if the opposite. In either case the moon goes on to cover a constantly increasing portion of the sun's surface. The total or annular eclipse begins at the moment when the distance of the centres of the two discs becomes equal to the difference of their apparent radii, which makes the circumferences of the discs touch internally. After some time, as the distance of the centres becomes again equal to and greater than the difference of radii, the eclipse becomes partial only. Calculation shows that 4h. 29m. 44s. is the longest possible duration of an eclipse at a place on the equator 3h. 26m. 32s., under the parallel at Paris. We understand, besides, that these phenomena may be shorter than that, by any amount. If, in place of examining the different phases of a solar eclipse, to an observer at one special place, we try to understand the phenomena which the eclipse will present everywhere, we shall discover them quite as readily. We must conceive the moon, in her motion round the earth, to carry with her the umbral and penumbral cones $B O B'$, $C O' C'$ (fig. 10), which we have previously mentioned. When, in consequence of this movement, the penumbral cone touches the earth (fig. 15), the eclipse begins at the point of contact. Almost immediately, the penumbral cone proceeds—covering more and more of the globe. Soon, the umbral cone touches the surface, and at that point it is that

Fig. 15.

we begin to observe, either a total or annular eclipse, since it is only this cone or its prolongation which can reach the earth. These two cones, proceeding together, cover successively different portions of the earth, passing from region to region. At the end of any time, the cone of the umbra—then that of the penumbra, again touch the surface, and, the instants when they do so close the total or annular and the partial eclipses respectively. Sometimes, in our atmosphere there are small isolated clouds which project a shadow over the sun, in the middle of places, all the rest of which is illuminated. These being generally in motion, we can see

ECL

the shadow move, often very rapidly over the earth. It is just in the same way, that the umbra of the moon, in total solar eclipses, changes its position on the earth, moving from one edge to the other of the illuminated hemisphere. Astronomers usually determine the general circumstances of a solar eclipse over the whole of

ECL

the world, beforehand, and, to show these results at once, they make a chart on which to mark its course. The next figure (fig. 16) shows the arrangement of such charts;—it represents the annular eclipse on the 1st April, 1764. The line AEC passes through all points where the eclipse has begun at the moment of sunrise, and

Fig. 16.

the line ADC , where it ends at that time. For all points, on AEC , the sun rose at the middle of the eclipse. Similarly, the lines AFG , AHG , AIG , contain those points respectively where sunset happened at the end, the beginning, or the middle of the eclipse. The narrow strip LL' , is the route which the prolongation of the moon's umbra pursued. We see that it passed to the north of the Cape Verd Islands, over the Canaries, and to the south of Madeira; that it scarce touched on the coast of Morocco, and then passed through Portugal, Spain, France, the Netherlands, Denmark, Sweden, Lapland, and Nova Zembla. The eclipse has been annular at Lisbon, Madrid, and Paris. On either side of the strip LL' , there has only been a partial eclipse, feebler and feebler, the farther the points of observation are from LL' . Over all points of the line MM , the eclipse was only 9 digits—over the line NN , 7 digits. Along PP again, 9; along QQ , 6; along

RR , 8; and along CSG , the edges of the discs merely touch, but there is no eclipse. Beyond CSG there has been no eclipse, although the sun has been above the horizon. The period of 18 years and 11 days, at the end of which the moon passes through the same positions in regard to the sun and to her nodes, is as useful in solar as in lunar eclipses. All that have been observed in one such period, are reproduced in the succeeding ones. There are some few changes, however, because the 223 lunations are not exactly equal to 19 synodical revolutions of the nodes. Observation shows, that, on an average, in the space of 18 years 11 days, there are 70 eclipses, 29 lunar and 41 solar. There are never more than 7, or fewer than 2, in one year; if only two, they will be both solar. It is easy to see why solar eclipses are the more frequent. In fact, if we consider the cone AOA' enveloping the sun and earth, we know that the

ECL

moon must enter this cone at c, that there may be a lunar eclipse; but we see that it must penetrate this cone at d that there may be a solar

Fig. 17.

eclipse for some places of the earth; now, the transversal dimensions of the cone being greater at d than at c, it results, of necessity, that the moon should reach its surface oftener at d than at c, and that therefore solar eclipses should be the more frequent. But we must not believe that in any one special place more solar than lunar eclipses can be seen. A lunar eclipse is visible over more than a hemisphere, a solar one, only in part of a hemisphere, sometimes a very small part. This is the reason why there are more lunar than solar eclipses visible at one place, in spite of the greater frequency of the occurrence of the latter over the whole earth. We may understand this also, by noticing that the apparent diameter of the earth's umbra, taken at the distance of the moon, is much greater than that of the sun, and that, consequently, it must oftener happen that the moon, observed from any special place on the surface, should touch the earth's shadow, than the sun's disc. As for total solar eclipses, they are extremely infrequent in any one place, as we may readily see by considering how small is the shadow which the moon projects on the earth. The part of the earth covered successively by this shadow is but a very slight fraction of the whole space from which a solar eclipse may be observed. At Paris, for instance, there was only one total eclipse of the sun in the 18th century, that of 1724; and there will not be another till towards the end of the 19th. At London, for 575 years not one was witnessed, from 1140 to 1715; and, from 1715, no such eclipse has been seen again there. Total eclipses of the sun are very rare, very remarkable, and therefore very startling phenomena. The sudden disappearance of the great luminary, the source of our light and heat, naturally fills those who do not know why it must be, with alarm and dismay. When we know that, and that in a few moments the sun will reappear, our terror is lessened, but yet, involuntarily, when the darkness begins, we are seized with a vague fear. Whilst the sun is entirely hid, there appears all round him a certain darkness which seems very intense, because it comes almost instantaneously; but which is yet something very different from the darkness of night. The cone of the moon's shadow, though it does extend to a certain distance all round the place where we stand, cannot enclose the whole atmosphere above the horizon; it leaves round it a considerable mass of air, which receives the rays of the sun

ECL

directly, and reflects them back again, into the regions of the earth where the total eclipse is being observed; it follows that, instead of a complete darkness, there is a sort of twilight. The brightest stars and the chief planets become visible. The temperature of the air sinks rapidly some degrees. Animals show their terror, and many of them do as they are wont at the approach of night. As long as the total eclipse lasts, we see round the sun and moon a luminous crown, as in the figure. The moon is projected, as a black circle in the midst of this crown. It has been asked whether this

Fig. 18.

anneals be due to an atmosphere of the sun, which his brilliancy would not let us see, or whether it be not due to a very rare lunar atmosphere? To resolve the question, we have sought to ascertain whether the luminous crown follows the moon as it moves over the sun, during the whole time of eclipse, or if it remains behind, preserving its position relative to the sun. Hitherto, observation has given no certain answer. During the total eclipse of 8th July, 1842, visible in the South of France, when astronomers were about to note this, an unforeseen phenomenon arrested their attention. Protuberances of a violet, rose colour appeared round the moon, as seen in the figure. What is the cause of these, for they have been observed in various places by various observers? We cannot tell. Several ideas have been started, but we cannot accept any of them positively. If, for instance, they were due to solar mountains, as is most improbable, the height of these mountains would be prodigious, as the figure will enable us to judge. Partial eclipses of the sun, like the phases which go before and follow the total or annular eclipses, do not produce effects by any means so marked. When the eclipse is a large one, the light is very sensibly diminished, though as long as any portion of the disc is uncovered, it remains very considerable. It is impossible, in observing partial solar eclipses, to look at the sun directly; we must do so through coloured glass or glass smoked by being held over a flame. If we turn to his disc, during such an eclipse,

ECL

a plate or card in which a hole is bored, and set a screen behind it, or set it before a wall, we obtain, on the principle of the camera, a representation of the form of the sun, with its indentation by the moon, on the screen or wall. This is a very simple way of observing the eclipse in its progress. The foliage of trees often allows some rays of the sun to pass which may illu-

FIG. 19

minate some parts of the ground in the middle of the shadow of the foliage. The interstices then do just what the card or plate with the hole in it does; it follows, that those parts of the ground, which are illuminated through them, take a form depending on that of the sun's disc. Usually, as the sun's disc is circular, and the

FIG. 20.

rays fall obliquely on the ground, the form of these illumined parts is elliptical. During solar eclipses, the more or less distinct indentation of the disc, is exhibited in these bright spaces, and they take the form of ellipses, indented all on the same side, and by the same amount. This is very distinct, and it is very difficult to help it, being struck, even if it has been anticipated.

ECL

(4.) *Prediction of Solar Eclipses.*—The period of 18 years 11 days, which served the old astronomers for lunar, serves also for solar eclipses. But, though it can indicate whether or not there will probably be an eclipse, it does not at all indicate whether that eclipse will or will not be visible, and, if so, to what extent. This difference flows from the different nature of the two phenomena. A lunar eclipse is due to the actual loss by the moon of her light, and is visible wherever she is, and everywhere in the same degree. In the solar eclipse, the sun loses none of his; the moon prevents observers from seeing part or the whole of his disc, and that portion differs with their position. As the period mentioned is not rigorously accurate, and as the rotation of the earth brings different points successively within the moon's shadow, we may see how the eclipses which happen at one place in one such period may not occur at the same place, in the next. Thus, the ancients were obliged, with their imperfect methods, to confine their predictions to lunar eclipses. They continued unable to discover any law among the complex phenomena of the recurrences of solar eclipses. But we can now predict the solar as well as the lunar. In this case, however, the calculations are much more complex. If we seek to predict the character of the eclipse over the whole hemisphere, the complication thus introduced is enormous, even for one place it is very considerable. In fact the parallaxes of the sun and moon are of the highest importance here, since, if we were at the earth's centre, we should generally see the two stars occupying different portions in the sky, and since, from this point, the eclipse might appear a very different one from what it does at our actual position. Now, the parallax in altitude, of the moon—which enables us to pass from the one of these positions to the other—varies considerably at the different hours of the day, and so throughout the duration of any one eclipse. The parallax in altitude, at the beginning of an eclipse, is not, in short, the same as at the end of it. This occasions much more numerous calculations, although not in any way more difficult, than in the other case. We shall give no example, because of its tediousness. It is enough to say, that it is by comparison of the relative positions of sun and moon in the sky, at successive very short intervals (e.g. 10 minutes), that we determine the various dates of the beginning, middle, and end of the eclipse, &c. It is to be noted, that though we have to consider the parallaxes, we have not to take account of refraction. In fact, the effect of it will be nearly the same upon both the sun and moon at the time of the eclipse. Hence, we may calculate the times when the sun and moon would appear together, were there no atmosphere, seeing that refraction only lifts them both up for some little distance in the sky—not changing their relative positions.

ECL

Ecliptic. The circle in the visible heavens described by the sun in his annual course. Every day he seems to describe a complete circular figure in the sky, returning next morning to the place from which he set out. But, if his exact position be noted, it will be found that he does not so return, but that his motion is in a line something in the form of the spiral in a spring of several coils, bringing him nearly back to the same place. In fact, he has moved some distance. If he remained quite stationary relative to the axis of the earth for a whole day, the diurnal revolution would give him a complete apparent circular path. It does not so, because his position has changed during the 24 hours of our rotation. If the points at which he is successively in the sky be noted, a complete circular figure called the ecliptic, representing the sun's apparent or the earth's real path of annual revolution, will be drawn. This is called the ecliptic. Celestial longitude and latitude (*q.v.*) are unfortunately measured from the ecliptic and its pole, as terrestrial longitude and latitude from the equator and its pole. This want of uniformity tends to confusion. The better known circle, the equator, is usually taken as a sort of circle of reference, and the position of others is given by means of it. The ecliptic is defined in this way, as a circle cutting the circle of the equator, on an average at an angle of about $23^{\circ} 27' 54''$. This value is, however, not permanent. The attempt to measure it was first made by Eratosthenes, about 270 B.C. (at least except among the Eastern nations; Tchou Kong, the regent of China, measured it about 1100, and his result is only about $2\frac{1}{2}$ minutes greater than it should have been); and he made it $23^{\circ} 51' 13''$. It was found by various astronomers, after him, to be $23^{\circ} 35'$; $23^{\circ} 29' 47''$; $23^{\circ} 29'$, &c. The constant decrease was noticed. It was doubted for long whether the obliquity did not remain constant, only that astronomical errors of observation had crept in: not until the theory of gravitation was established, was the question finally settled. Euler shows that it is decreasing, and must be so for a very long period. The formula was subsequently found to be $\theta = 23^{\circ} 27' 54'' \cdot 8 - 0'' \cdot 488566 t - 0'' \cdot 000005 t^2$, where θ is the obliquity and t the number of years counted from 1800. This formula gives a sufficiently accurate result for about 1200 years behind or before: but, after that, other terms of the formula, introducing t^3 , require to be taken into account.—The physical cause of this change is the obliquity of the ecliptic is the action of the other planets, especially Jupiter, Mars, and Venus, upon the mass of the Earth. The variation, however, is, like most variations of nature on so large a scale, one that oscillates within narrow limits. If the equator and ecliptic came together, we should have no seasons whatever, and the whole economy of our world would be disturbed.

ELA

Eidograph. See PANTOGRAPH.

Elasticity is the property which bodies possess of occupying, and tending to occupy, portions of space of determinate volume, or determinate volume and figure, at given pressures and temperatures, and which, in a homogeneous body, manifests itself equally in every part of appreciable magnitude.

2. An *Elastic Pressure* is a force exerted between two bodies at their surface of contact, or between two parts into which a body either is divided or is capable of being divided at the surface of actual or ideal separation between those parts. The magnitude of an elastic pressure is stated in *units of weight per unit of area* of the surface at which it acts.

Values of various units of Elastic Pressure in pounds avoirdupois per square foot.

One pound per square inch.....	144
One inch in height of a mercurial column, at the temperature of melting ice.....	70.73
One atmosphere of 29.922 inches of mercury,	2116.4

3. The elasticity of a *perfect fluid* is such that its parts resist change of volume only, and not change of figure; whence it follows, that the pressure exerted by a perfectly fluid mass is wholly perpendicular to its surface at every point: principles which form the basis of hydrostatics and hydrodynamics.—Fluids are either gaseous or liquid. A *Gaseous Fluid* (popularly called an "Elastic Fluid") is one whose parts (so far as is known by experiment) exert a pressure against each other and against the vessel containing them, how great soever the volume to which they are expanded. See HEAT—MECHANICAL ACTION OF, sec. 9, 10, 11, 35; also BAROMETER, VAPOUR and SOUND.

4. The elasticity of a *Perfect Liquid* resists change of volume only, and differs from that of a gaseous fluid chiefly in this: that the greatest variations of the pressure which it is possible to apply to a liquid mass produce very small variations of its volume.

5. The *Compression* undergone by a liquid mass in consequence of the application of a given pressure over its surface, is measured by the ratio of the diminution of volume produced by the given pressure to the entire volume of the mass: a ratio which is always a very small fraction.—The *Compressibility* of a given liquid is the compression produced by a unit of elastic pressure; in other words, the ratio of a compression to the pressure producing it.—The *Modulus or Coefficient of Elasticity* of a liquid is the ratio of a pressure applied to and exerted by the liquid, to the accompanying compression, and is therefore the reciprocal of the compressibility.—The compressibility of a liquid is ascertained by means of an instrument called a *Piezometer* (*q.v.*)—The following empirical formula for the compressibility of pure water at any temperature between 32° and 128° Fahrenheit has been deduced by Mr. Rankine from the experiments of M. Grassi

ELA

(Comptes Rendus, XIX.; Philos. Mag. June 1851).
—Compressibility per Atmosphere,

$$= \frac{1}{40 (\tau + 461^\circ) \cdot D}$$

τ , temperature in degrees of Fahrenheit. D , density of water at that temperature under one atmosphere, the maximum density of water under the pressure of one atmosphere being taken as unity. At the temperature of maximum density, 39° Fahr., the compressibility of water per atmosphere is 0.00005, and its modulus of elasticity, 20,000 atmospheres.

Compressibilities of some Liquids, per Atmosphere, from M. Grassi's experiments.

Saturated aqueous solution of nitrate of potash	0.0000806565

Ether.....	0.00011187 to 0.00013078
Alcohol.....	0.00008245 to 0.00008587
The compressibility of ether and alcohol increases with the pressure.	

6. A *Solid* body, besides resisting change of volume like a liquid, possesses also *Rigidity*, or the property of resisting change of figure.—As in the case of liquids, the utmost alteration of volume of which a solid body is capable by any pressure which can be applied to it, is always a very small fraction of its entire volume.—The elastic pressures at the surface of a solid body or particle are not necessarily normal, but may have any direction, from normal to tangential.

7. In popular language the words *Strain* and *Stress* are applied indifferently to denote either the system of pressures at the surface of a solid body whereby its volume and figure are altered, or the alteration of volume and figure of the body and its parts thereby produced. For the sake of clearness in scientific language, certain authors have recently endeavoured to appropriate the word *Strain* to the alterations, of what nature soever, in the volume and figure of a solid body and of its parts, produced by forces applied to it, and the word *Stress* as synonymous with Elastic Pressure, or combination of elastic pressures. This nomenclature will be used in the present article.—*Fracture* of a solid occurs when a strain is carried so far as to cause actual division of the solid into parts. The strains and fractures to which a solid, considered as a whole, is subject, may be classified according to the following table. To each kind of strain there corresponds a kind of stress; being the external force which produces that strain and the equal and opposite force wherewith the solid resists that strain.

	Strain.	Fracture.
Longitudinal.	{ Extension ..	Tearing.
	{ Compression ..	Crushing and Cleaving.
Transverse....	{ Distortion ..	Shearing.
	{ Torsion ..	Wrenching.
	{ Bending ..	Breaking across.

ELA

8 A body is said to be *Perfectly Elastic* which, if strained at a constant temperature by the application of a stress, recovers its original volume, or volume and figure, when such stress is withdrawn, and gives out, during such recovery, a quantity of mechanical work exactly equal to that originally exerted in producing the strain. Deviations from this property constitute *Imperfect Elasticity*. Gases, and liquids perfectly free from viscosity, are perfectly elastic.—The elasticity of every solid is sensibly perfect when the strain does not exceed a certain limit. This has been proved to be the case even for solids so plastic as moistened clay. For every solid there are limits, which if a strain exceed, *set*, or permanent alteration of volume or figure, is produced; and such *Limits of Elasticity* are less, and often considerably less, than the strains required to produce fracture. It has been proved by Mr. Hodgkinson that these limits depend on the duration of the strain, being less for a long-continued strain than for a brief strain. The *elasticity of volume* in solids is in general much more nearly perfect than the *elasticity of figure*. It is true that the density of many metals is permanently increased by hammering, rolling, and wire-drawing, and that of some other materials by intense pressure (Fairbairn; Report of the British Association, 1854;) but the stresses which operate during these processes are very great.—The degree to which the elasticity of a solid substance is imperfect is sometimes measured by means of experiments on the disappearance of vis-viva during the collision of two balls of the substance experimented upon. The mechanical work expended in permanently altering the volume or figure of an imperfectly elastic body produces heat according to the same law with work expended in friction. See HEAT, MECHANICAL ACTION OF. A body which is capable of undergoing great alterations of figure, and whose elasticity of figure is very imperfect, is a *plastic solid*. The gradations are insensible between plastic solids and *viscous liquids*, in which there is a resistance to change of figure, but no tendency to recover any particular figure.—*Rise of Temperature*, so far as we yet know, increases elasticity of volume in all substances, and at the same time diminishes the amount and the perfection of elasticity of figure, so as to make solids more plastic and liquids less viscous.—See HEAT.

9. The *Ultimate Strength* of a solid is the stress required to produce fracture in some specified way. The *Elastic Strength* is the stress required to produce the greatest strain of a specific kind, consistent with perfect elasticity. Strength, whether ultimate or elastic, is the product of two quantities, which may be called *Toughness* and *Stiffness*. *Toughness*, ultimate or elastic, is here used to denote the greatest strain which the body will bear without fracture, or without imperfection of elasticity, as the case may be:—*Stiffness*, which

might also be called *Hardness*, is used to denote the ratio borne to that strain by the stress required to produce it,—being, in fact, a *modulus of elasticity* of some specified kind. *Malleable* and *Ductile* solids have ultimate toughness greatly exceeding their elastic toughness. *Brittle* solids have their ultimate and elastic toughness equal or nearly equal.—*Resilience* or *Spring* is the quantity of *mechanical work* required to produce the limiting strain of perfect elasticity, and is equal to the product of that strain, by the *mean stress* in its own direction which takes place during the production of that strain:—such stress being either exactly or nearly equal to one-half of the stress corresponding to the limiting strain. Hence the resilience of a solid is exactly or nearly one-half of the product of its elastic toughness by its elastic strength; in other words, one-half of the product of the square of its elastic toughness by its stiffness.—Each solid has as many different kinds of Toughness, Strength, and Resilience as there are different ways of straining it.

10. The theory of the elasticity of solids has been reduced to a body of *mathematical principles* applicable to those cases in which the strains of the particles of the body are so small, that quantities in the stresses depending on the squares, products, and higher powers of the strains may be neglected without appreciable error, and that, consequently, *Hooke's Law*,—"ut Tensio sic Vis"—is sensibly true for all relations between strains and stresses. This condition is fulfilled in nearly all cases in which the strains are within the limits of perfect elasticity—the exceptions being a few substances, very pliable and at the same time very tough, such as caoutchouc. The mathematical theory, as thus limited, consists of three parts, viz., the Resolution and Composition of Strains, the Resolution and Composition of Stresses, and the relations between Strains and Stresses.

11. Let a solid of any figure be conceived to be ideally divided into a number of indefinitely small cubes by three series of planes parallel respectively to three co-ordinate planes. Each such elementary cube is distinguished by means of the distances, x, y, z , of its centre from the three co-ordinate planes.—If the solid be strained in any manner, each of the elementary cubical particles will have its dimensions and figure changed, and will become a parallelopiped which may be right or oblique—its size being conceived to be so small, that the curvature of its faces is inappreciable.—The *Simple* or *Elementary Strains* of which a particle, cubical in its free state, is susceptible, are six in number, viz.:—three *longitudinal* or *direct strains*, being the three proportional variations of its linear dimensions, which are elongations when positive, and compressions when negative; and three *transverse strains*, being the three *distortions*, or variations of the angles between its faces from right angles, which are considered as positive or negative ac-

cording to some arbitrary but fixed rule, and are expressed by the proportions of the arcs subtending them to radius. When the values of these six strains for every particle are expressed by functions of the co-ordinates x, y, z , the state of strain of the solid is completely expressed mathematically.—The six elementary strains, in the cases to which the theory is limited, are very small fractions.—The method of reducing the state of strain of the solid at a given point, as expressed by a system of six elementary strains relatively to one system of rectangular axes, to an equivalent system of six elementary strains relatively to a new system of rectangular axes, is founded on the following theorem. Let α, β, γ , be the longitudinal strains of the dimensions of a given particle along x, y, z , λ, μ, ν , the distortions of its angles in the planes yz, zx, xy . Conceive the surface of the second order whose equation is

$$\alpha x^2 + \beta y^2 + \gamma z^2 + \lambda yz + \mu zx + \nu xy = 1.$$

Transform this equation so as to refer the same surface to the new axes of co-ordinates; the six coefficients of the transformed equation will be the elementary strains referred to the new axes. Other ways of resolving strains have been pointed out by Professor W. Thomson, *Cambridge and Dublin Mathematical Journal*, May, 1855.—The sum of the direct strains $\alpha + \beta + \gamma$, represents the cubic dilatation of a particle when positive, and the cubic compression when negative. The state of strain of a transparent body may be ascertained experimentally by its action on Polarized Light. On this subject experiments have been made by Fresnel, Sir D. Brewster, M. Wertheim, and Mr. Clerk Maxwell.

12. Let ξ, η, ζ , be the projections, parallel to x, y, z , respectively, of the *displacement* of a particle in a strained solid from its position when the solid is free, expressed as functions of x, y, z . Then

$$\alpha = \frac{d\xi}{dx}; \quad \beta = \frac{d\eta}{dy}; \quad \gamma = \frac{d\zeta}{dz};$$

$$\lambda = \frac{d\zeta}{dy} + \frac{d\eta}{dz}; \quad \mu = \frac{d\xi}{dz} + \frac{d\zeta}{dx};$$

$$\nu = \frac{d\eta}{dx} + \frac{d\xi}{dy}.$$

13. The elastic pressures exerted on and by an originally cubical particle, which constitute the state of stress of the solid at the point where that particle is situated, may be resolved into six *Elementary Stresses*, viz.:—three *Normal Stresses*, perpendicular respectively to the three pairs of faces, and tending directly to alter the three linear dimensions of the particle—and three pairs or *Tangential Stresses*, that is, pressures acting *along* the double-pairs of faces to which they are applied, and tending directly to alter the angles made by such double-pairs of faces. To reduce

the state of stress at a given point expressed by a system of six elementary stresses referred to one system of rectangular co-ordinates to an equivalent system of elementary stresses referred to a new system of rectangular co-ordinates, let P_1, P_2, P_3 , be the three normal stresses, and Q_1, Q_2, Q_3 , the three tangential stresses; conceive the surface where equation is,

$$P_1x^2 + P_2y^2 + P_3z^2 + 2Q_1yz + 2Q_2zx + 2Q_3xy = 1;$$

transform this equation so as to refer the same surface to the new set of axes; the six coefficients of the transformed equation will be the six elementary stresses referred to the new axes. For the complete investigation of this subject, see M. Lamé's *Leçons sur la Théorie Mathématique de l'Elasticité des Corps Solides*, Paris, 1852.

14. The *Potential Energy of Elasticity* of an originally cubic particle in a given state of strain is the *work* which it is *capable of performing* in returning from that state of strain to the free state; and is the product of the volume of the particle by the following function:—

$$U = \frac{1}{2} (\alpha P_1 + \beta P_2 + \gamma P_3 + \lambda Q_1 + \mu Q_2 + \nu Q_3).$$

This function was first employed by Mr. Green, *Cumbridge Transactions*, vol. vii.

15. According to Hooke's Law each of the six elementary stresses P_1 , &c., may, without sensible error, be treated as a linear function of the six elementary strains, α , &c., each multiplied by a particular *Coefficient* or *Modulus of Elasticity*. By expressing all the stresses in terms of the strains, the Potential Energy U is transformed into a homogeneous quadratic function of the six elementary strains, which must have twenty-one terms, and consequently *twenty-one Coefficients*, multiplying respectively the six half-squares, and the fifteen binary products, of the six elementary strains. The coefficient of $\frac{1}{2} \alpha^2$ in U is that

of α in P_1 ; the coefficient of $\alpha \beta$ in U is that of α in P_2 and also that of β in P_1 ; and so on.

16. According to Hooke's Law also, each of the six elementary strains may be treated, without sensible error, as a linear function of the six elementary stresses, so as to transform U to a homogeneous quadratic function of the elementary stresses P_1 , &c., having twenty-one terms, and twenty-one coefficients expressing different kinds of *Pliability*. The word "Pliability" is here used in an extended sense, to include liability to alteration of figure of every kind, whether by elongation, linear compression, or distortion.

17. Coefficients, whether of Elasticity or of Pliability, may be thus classified:—*Direct*, or *Longitudinal*, when they express relations between longitudinal strains, and normal stresses in the same direction.—*Lateral*, when they express relations between longitudinal strains, and normal stresses in directions at right angles to the

strains.—*Transverse*, when they express relations between distortions, and tangential stresses in the same direction.—*Oblique*, when they express any other relations between strains and stresses.

18. An *Axis of Elasticity* is any direction in a solid body, with respect to which some kind of symmetry exists in the relations between strains and stresses. Various kinds of axes have been pointed out by Mr. Haughton, *Trans. Roy. Irish Acad. XXIII.*, and Mr. Rankine, see *Philosophical Transactions*, 1855. In particular, an *Axis of Direct Elasticity* is a direction in a solid body such, that a longitudinal strain in that direction produces a normal stress, and no tangential stress on a plane normal to that direction. Every such axis is a direction of maximum or minimum direct elasticity relatively to the directions adjacent.—By the aid of the Calculus of Forms, and of an improvement in the Geometry of Oblique Co-ordinates, it has been shown by Mr. Rankine that every homogeneous solid must have *at least three* axes of Direct Elasticity, which may be rectangular or oblique with respect to each other,—that the number of such axes increases as the symmetry of the action of elastic forces becomes greater,—and that their various possible arrangements correspond exactly with those of the normals to the faces and edges of the various *Primitive Crystalline Forms*.

19. In an *Isotropic* or *Amorphous Solid* the action of Elastic Forces is alike in all directions. Every direction is an Axis of Elasticity. The coefficients of Oblique Elasticity and Oblique Pliability are all null. The number of different coefficients of Elasticity, and of different coefficients of Pliability, is three. The following notation and equations show their relations to each other:—

ELASTICITIES.

$$\text{Direct,..... } A = \frac{\alpha - b}{\alpha^2 - \alpha b - 2b^2};$$

$$\text{Lateral, } B = \frac{b}{\alpha^2 - \alpha b - 2b^2};$$

$$\text{Transverse, } C = \frac{A - B}{2};$$

$$\text{Elasticity of volume, } \frac{1}{b} = \frac{A + 2B}{3}.$$

PLIABILITIES.

$$\text{Direct, } a = \frac{A + B}{A^2 + AB - 2B^2};$$

(otherwise, the extensibility).

$$\text{Lateral, } b = \frac{B}{A^2 + AB - 2B^2};$$

$$\text{Transverse, } c = \frac{1}{C} = 2(a + b);$$

$$\text{Cubic compressibility, } d = 3a - 6b.$$

The quantity to which the term "*Modulus of*

Elasticity was first applied by Dr. Young, is the reciprocal of the Extensibility, or Longitudinal Pliability; that is to say,

$$\frac{1}{E} = A - \frac{2B^2}{A+B}.$$

This quantity expresses the ratio of the normal stress on the transverse section of a bar of an isotropic solid to the longitudinal strain, *only when the bar is perfectly free to vary in its transverse dimensions, but not under other circumstances.* In the commonly received theory of the strength of materials, it has been erroneously taken for granted that Young's Modulus expresses that ratio under all circumstances. The magnitude of some of the errors to which this assumption leads is shown in Mr. W. H. Barlow's experiments on the flexure of Cast Iron Beams, (see *Philosophical Transactions*, 1855). The values of Young's Modulus have been determined experimentally for almost every solid substance of importance, and tables of them have been published in treatises on mechanics. (See, in particular, *Leçons sur la Résistance des Matériaux*, par le Général Morin, Paris, 1853.) Those of the Transverse Elasticity σ have been deduced from experiments on Torsion, of which many have been made, especially by Bevan and Savart. The only complete sets of Coefficients of Elasticity and Pliability which have yet been computed are those for Brass and Crystal, deduced from the experiments of M. Wertheim, (*Annales de Chimie*, 3d series, vol. 28), and are as follows: the unit of pressure being *one pound on the square inch* :—

	Brass.		Crystal.
A	22,224,000	8,522,800.
B	11,570,000	4,201,400.
C	8,227,000	2,159,100.
$\frac{1}{E}$	15,121,000	5,643,800.
$\frac{1}{\sigma}$	14,200,000	5,746,000
$\frac{1}{\sigma}$	0.000000699	0.000001740.
$\frac{1}{\sigma}$	0.000000239	0.000000575.
$\frac{1}{\sigma}$	0.0000001877	0.0000004631.
$\frac{1}{\sigma}$	0.000000661	0.000001772.

20. The general problem of the *Internal Equilibrium of an Elastic Solid* is this:—given the free form of a solid, the values of its coefficients of elasticity, the attractions acting on its particles, and the stresses applied to its surface: to find its change of form, and the strains of all its particles. This problem is to be solved, in general, by the aid of an ideal division of the solid (as already described) into molecules rectangular in their free state, and referred to rectangular co-ordinates. For isotropic solids, some particular cases are most readily solved by means of spherical, cylindrical, or otherwise curved co-ordinates. (See Lamé, *Leçons*, &c.; Maxwell, *Edinburgh Transactions*, XX.; Rankine, *Manual of Applied Mechanics*.)

21. Many attempts have been made to simplify the theory of elasticity by the aid of *Hypotheses* as to occult molecular structures in bodies. That most cultivated has been the hypothesis of Boscovich, that bodies are systems of physical points or centres of force, occupying space solely in virtue of attractions and repulsions between them. A necessary consequence of this hypothesis is, that for all isotropic bodies, $A=3C$. This consequence is contradicted by experiment: therefore the hypothesis is untenable. Another hypothesis is that of Æpinus, Franklin, Mossotti, and others, which, to atomic nuclei, like the physical points of Boscovich, superadds elastic atmospheres enveloping them. As to the Hypothesis of Molecular Vortices, see HEAT, MECHANICAL ACTION OF, secs. 84, 85. This hypothesis has been serviceable in the theory of the relations between elasticity and heat;—but when the theory of elasticity is considered in itself, it is unquestionably best to avoid hypotheses altogether.

22. The subject of Elasticity has been investigated mathematically and experimentally by a multitude of authors too great to be completely enumerated here; but amongst them may be specified the names of Galileo, Leibnitz, Huyghens, Hooke, Boyle, Newton, the Bernouillis, Euler, Boscovich, Coulomb, Dupin, Marriotte, Robison, Young, Rennie, Bevan, Tredgold, Brewster, Fresnel, Gauss, Savart, Navier, Poisson, Oersted, Colladon, Sturm, Mossotti, Cauchy, Lamé, Clapeyron, Grassi, Regnault, Wertheim, St. Venant, Poncelet, Morin, Green, Stokes, M'Cullagh, Haughton, Kelland, Hodgkinson, Fairbairn, P. Barlow, W. H. Barlow, Forbes, W. Thomson, J. Thomson, Gordon, Jelllett, Maxwell, Rankine. As to the vibrations of Elastic Solids, see SOUND.

Electrical Egg: long known as an interesting philosophical toy, and a favourite in the popular lecture-room. As in other by no means unfrequent cases, however, it has suddenly assumed the position of a philosophical instrument of high import, revealing phenomena worthy to arrest the attention of such men as Grove, Gassiot, Rwhmkorff, Quet, Plücker, and Dr. Robinson of Armagh. We shall rapidly indicate the nature of the appearances that are sustaining inquiries so sedulous and grave, and present afterwards a *résumé* of the present state of the problems thus originated.

I. The INSTRUMENT itself is exceedingly simple and well known. It consists of an oval glass vessel, like that in fig. 1, so constructed, that the air or gas within it can be attenuated by means of connection with an air-pump; and through which approximate vacuum an electric discharge may be passed by aid of the rods indicated in the same figure. At the ends of these rods, balls are represented, as the positive and negative electrodes; but these may be replaced by platinum points, or by discs,

according to the object of the experimenter.

The primary requisition made of the instrument, being merely that it permit an electric spark or current to pass through an attenuated gas, it is clear that the form of it is by no means confined to the one represented; and this form has been varied accordingly. It occurred to Mr. Gassiot, that by employing the Torricellian vacuum, and then hermetically sealing the tube, the cambrons appendage of the air-pump might be dispensed with. He carried out his idea most successfully, and with a rich harvest of results. Their shape is shown in figs. 2 and 3, where the bent platinum wires constitute point-electrodes in the one case, and external strips of foil in the other, for the induced discharge. But

Fig. 1.

the most important addition to our instrumental resources in this case, unquestionably came from M. Geissler of Bonn, who not only

succeeded in sealing tubes filled with varieties of gases of all degrees of density, but conceived the idea of diversifying the shape of the tubes, so that the effects of another element might be tested and determined. He has made them accordingly as globes, as pear-shapes—one of which is drawn in fig. 10 (see below). One of his favourite forms is rather complex;—the centre is an ellipsoid, not unlike the original egg: the two ends containing the platinum electrodes are globes, and these are connected with the central ellipsoid by tubes of different diameters. In devising these forms, most of which present peculiar phenomena,—Geissler has had the great advantage of the aid and counsel of Plücker. Mr. Ladd, of Chancery Lane, London, has recently imported a number of Geissler tubes, so that they may easily reach the hands of British inquirers.

II. Turn now to the PHENOMENA.—The general phenomena are these. The electrical egg, as known originally, was supposed to manifest no appearance, save the brilliant one represented in fig. 1. After the air had been sufficiently exhausted, and a succession of electric sparks was being sent through the approximate vacuum, the negative pole (the lower one in the figure)

Fig. 2.

Fig. 3.

became surrounded by a blue aureola, while from the positive or upper pole, streams or billows of superb fiery red passed downwards to the neighbourhood of the negative pole, from which, however, they were always separated by a dark space, varying in breadth with change of circumstances. This fine experiment could be prolonged for hours—as long, indeed, as the vacuum was kept up, and the succession of sparks continued. It was commonly employed to indicate the probable nature of the northern auroras.—In 1852, however, the phenomenon assumed quite another aspect. An observation on the part of Mr. Grove—which must have been as accidental, and may yet prove as fertile as the famous one by Malus—called his attention to the interior structure of these developments of light. He found that, in certain circumstances of exceedingly frequent occurrence, the light is *stratified*. The blue envelope of the negative pole is not single; but consists of at least three envelopes, the central one being the darkest. It is, however, in the streamers from the positive pole that this stratification is most distinctly seen. Its aspects vary with circumstances; but fig. 4 may be accepted as a sufficiently characteristic eye sketch of

its more distinctive features. On filling the tubes with the different gases, the phenomena become perplexingly diversified; nor perhaps is the time yet come for a sufficiently simple classification of their appearances. There are, however, two elements essential to the production of the phenomena, that must exercise a principal sway, viz., the power of the electric current or of the electromotor, and the quality of the attenuated gas. Other circumstances interfere; for instance, the quality of the gas may be changed by the persistent action of the current, *e. g.*, Oxygen may pass into Ozone, and compound gases are generally decomposed. Of these circumstances, however, we shall not attempt to take account; and in our short exposition we shall largely follow the track of Dr. Robinson, who has examined the subject with his usual

Fig. 4.

magacy and faithfulness. (See *Proceedings of the Royal Irish Academy* for January and December, 1846, and *Philosophical Magazine* for April, 1859).

The following diagram, fig. 5, will impress far better than any description, the phenomenon as

Fig. 5.

obtained by Dr. Robinson, when the medium in the receiver was attenuated pure Hydrogen. The large upper ball is the positive electrode; the negative electrode a point, below which a disc had been placed. The disc and stem of the negative electrode had its usual three envelopes; but the issue from the ball seems to have been of very great splendour. As the woodcut shows, it was trumpet-shaped, and consisted of a succession of menisci, separated from each other by about a quarter of an inch. This mass of menisci was also in rotation around the longitudinal axis. Now these phenomena are common to all such experiments. In all cases we have the menisci separated by these dark bands; but when the power is high, their curvature is reversed towards the end of the positive stream. In all cases we have their rotation, and the quiescence of the light around the negative electrode, which is likewise invariably divided into two envelopes, separated by a dusky interval.

The foregoing phenomena, therefore, must be owing to the only agency invariable in their production, viz., a discharge through an imperfect but mobile conductor. — The manner of discharge, which seems to facilitate the evolution of these ap-

pearances, is stated by Dr. Robinson to be the following:—1. The electrodes should be guarded points, that is to say, pointed platinum wires, surrounded by small glass tubes up to the very point. Geissler, we believe, always employs such.—2. The positive electrode should be the upper one. In the reverse arrangement, the ascending currents of heated air seem to cause confusion.—3. A very weak electromotive power will give no strata or menisci; while, on the other hand, a very strong force conceals them. A spark of a *tenth*, or even a *fifth* of an inch, fails to evolve them even in a Torricellian vacuum: very powerful discharges, again, cause the bright streaks to throw out cloudy appendages into the dark intervals; and sparks of five inches altogether overcome that resistance of the imperfect conduction to which the phenomena are probably owing,—entirely filling these intervals with light. It is found also that a more perfect attenuation of the medium compensates to a certain degree for the greater feebleness in the discharge.

If from these general phenomena and their conditions, we turn to the variations due to the use of different gases as media, condensed description becomes exceedingly difficult. There are, however, two phenomena even here, of a comparatively general nature, that ought to be especially noted. (1.) In many cases the rarified gases became *phosphorescent* under the influence of the discharge; that is to say, they continue to give out light after the cessation of that discharge. The circumstances under which such appearances take place are now being studied by Edmund Becquerel. This physicist thinks that he can distinguish two sorts of *persistence*.—*First*, in the case of rarefied hydrogen, sulphuretted hydrogen, protoxide of nitrogen, and chlorine, faint gleams of persistence are discerned; but the action appears *limited to the internal surface of the glass tube*. Becquerel shows clearly enough that this cannot be due to *phosphorescence of the glass itself*; “therefore,” he concludes, “the effect presented by tubes containing these gases appears to be the result of the *electrization of the glass*, or of the adherent gaseous stratum.” It is not likely to be due to the electrization of the glass, because it does not appear in all cases when an inductive current is transmitted through a glass tube.—*Secondly*, with oxygen, with sulphurous acid gas, with air slightly impregnated with phosphorus, &c., the effect is different. When an inductive discharge passing through rarefied oxygen, for instance, is suddenly stopped, the whole tube appears to be illuminated with a yellow tint that persists for several seconds after the interruption, and decreases with more or less rapidity until it disappears. The illuminating action, as seen in such cases, evidently takes place between the actual molecules of the gas, and does not pass along the walls of the tube, for on making use of *spheres* of large capacity, instead of tubes,

the entire mass of the gas becomes opaline. Becquerel remarks that the phenomenon probably depends on a peculiar action produced by the electric currents; for solar light, or even the electric light itself, does not give rise to any such phosphorescence. And he asks,—“Is it the result of vibrations impressed upon the molecules of the gases, or of a peculiar state of molecular tension persisting for a few moments, or of some other physical or chemical cause?”—(2.) With some media, the *fluorescent* rays of Mr. Stokes are very largely developed; employing others, not a trace of these rays can be discerned. For instance, when sufficiently rarefied atmospheric air is the medium, the fluorescent rays appear in abundance; and this also occurs if we substitute either of its main constituents, oxygen or nitrogen. On the other hand, hydrogen, sulphur, and carbon, are pre-eminently *anti-fluorescent*; hydrogen above them all. This singular quality accompanies the bodies named through their components, although sometimes the one and sometimes the other antagonist element prevails. Ammonia, for instance, is not sensibly fluorescent—the energy of the hydrogen prevailing over that of the nitrogen. But cyanogen is very fluorescent; the nitrogen in this instance overmastering the carbon. The remote cause of this well marked distinction is as yet unknown. Nevertheless, the enumeration just made cannot fail to suggest the inquiry,—whether fluorescence or anti-fluorescence depends in any degree on the *electro-negative or electro-positive character of the media*.

The strata, as we have said, greatly vary with the media, in the *colour* of their light. With atmospheric air the mass of the menisci are violet, and seem enveloped in a faint yellowish light. With hydrogen the light is a pale greenish-blue. With oxygen and nitrogen the colour is nearly the same as with common air. The oxygen, however, seems to pass into ozone. Nitrogen yields a positive light, more pink than that of air; while the envelopes of the negative electrode are indigo. On continuing the exhaustion in the latter case, the stream assumes the hue of a tawny brown. With carbonic oxide the stream is a bright green, yellowish at the positive end, bluish at the other. The stream is also green with carburet of sulphur, coal-gas, vapour of chloroform, vapour of alcohol, vapour of camphor, &c.; while livid blue and lilacs are evolved when the media are rarefied sulphurous acid gas, cyanogen, naphtha, ammonia, &c., &c. It remains for inquiry to determine how far these singular varieties may be found connected with the *density of the medium and its electric conducting power*.

III. Whatever the origin of the singular strise we have been describing, they may certainly be considered as lines or discs of electric force. And accordingly it was no rash conjecture that the neighbourhood of a magnet would make itself be felt by changes on their form and distribution. Gassiot has made several allusions to this new

part of the subject in the Bakerian Lecture of last year, establishing that stratifications arising from the direct discharge taken from two point electrodes, tend to rotate around the poles of a magnet, according to the well known law of magnetic rotations. When a reciprocating discharge is effected (obtained by coating two portions of a Torricellian tube externally with stripes of tin-foil), this discharge was found by Gassiot to be divided by the magnet—the two divisions having a tendency to rotate in different directions.—The most extensive experiments on the subject, however, are due to Plücker of Bonn. His memoirs—originally printed in Poggendorff's *Annalen*, No. ciii. and civ., and reproduced in an English dress in the second volume of the *Philosophical Magazine* of 1858—are so replete with new, curious, and diversified facts, that a satisfactory analysis of them within our brief space is impossible. Putting aside the changes of colour and every feature apparently depending on the varying nature of the medium, we shall treat only of the *constant* portion of the phenomena described. Plücker's researches refer mainly to phenomena connected with the strata and the negative electrode; but he has recorded valuable information also regarding the influence of magnetic action on the general current, or on the strata or menisci streaming from its opposite. Taking, for instance, a Geissler's tube of the form already described—viz.: a central ellipsoid, joined to two terminal spheres, within which the platinum points were placed—he states that on feeling the magnet approach, the light entering the ellipsoid becomes concentrated into a luminous arch, as in fig. 6, traversing the upper

Fig. 6.

part of the bulb in the equatorial plane of the magnet. On entering the ellipsoid, the stratification of the light became finer; at the upper part of the arch where the concentration of light was greatest, the dark intervals became more and more numerous and distinct—in fact, it presented the aspect of a *repelled arch of stratified light*.—Let us turn, however, to the researches of our physicist as to the strata around the negative electrode. It will be recollected that in the ordinary discharge, and in the ordinary phenomena of stratification, the negative electrode is surrounded in its immediate neighbourhood by an envelope of variously coloured and finely stratified light—separated by a dark interval from the stratified mass, streaming from the opposite pole. These fine layers are spherical when the positive

electrode itself is spherical: and they have a cylindrical form when the electrode projects into the tube as a wire. Now this stratification is quite broken up by the neighbourhood of a magnet, and thrown into the form of magnetic curves. Plücker, in all these inquiries, made much use of the irregular Geissler's tube, described above,

Fig. 7.

Fig. 8.

Fig. 9.

the diffuse violet light, collected into a horizontal, semilunar, bright, and uniformly luminous disc, bounded towards the tube by a well defined concave arch. On its opposite side this disc was enveloped by a narrow strip of beautiful bright green light, filling the curvatures of the glass. On changing the position of the tube, in reference to the magnet, the changes passed on this disc which are represented in figs. 8, and 9. In fig. 9 the disc rotated in the direction of the

arrow. Plücker concludes in general terms, that the planes or curved surfaces in which the diffused light spreading around the negative pole becomes concentrated, are formed of *lines of light which, proceeding from the separate points of the positive electrode, coincide with magnetic curves*. He employed next a long tube, tapering conically towards one end, laying it, as represented below, in an axial position. In fig. 10, one set of results are depicted. The stratification having refer-

Fig. 10.

ence to the positive electrode was modified only in this: it did not extend to the sides of the tube through its lower part. But the light belonging to the negative electrode was thrown into two concentric arcs, whose centres coincide with the middle point between the higher sur-

faces again assumed the form of magnetic curves. By the change thus effected, a remarkable commixture of the light occurs, and new colours appear when the ring opens and its light approaches that of the other part of the tube. The former of these was violet, the latter reddish; a beautiful blue light being formed on their approximation.— On inverting the poles, the light moves backwards and forwards in the neighbourhood of the negative electrode, and collects at the place where the surface formed by magnetic curves touches the glass.

Fig. 11.

faces of the two armatures. Move now the tube to the position shown in fig. 11, and the phenomena are wholly changed. These two arcs have

Plücker has been able farther to discern the precise agreements of these curious phenomena with the well established dynamical relations existing between electric currents and the magnetic force. The gas through which the current passes must be viewed physically as simply an *absolutely flexible* conductor: and Plücker first lays down the following new electro-magnetic

principle:—"If an absolutely flexible conductor, traversed by a current, is subjected to the action of any system whatsoever of magnetic forces, it is necessary, and at the same time sufficient for equilibrium, that the current assume the form of a negative curve." Now there are three sets of circumstances under which this principle may act with different results:—(1.) Suppose the electric discharge to take place between two fixed points, as in the case of the common voltaic arch. Under influence of a magnet, this arch will take the form of a magnetic curve, if its two extremities lie on the same magnetic curve. If this is not the case, curious transformations occur not hitherto investigated.—(2.) One of the extremities of the discharge may be fixed, while the other is merely under the condition of being somewhere on a given surface. This happens with the luminous discharge around the negative electrode in Geissler's tubes—the discharge then terminating at one side in that electrode, and at the other in the internal surface of the glass. From this condition all the phenomena discovered by Plücker, connected with that electrode, are readily deducible.—(3.) Or lastly, both extremities of the discharge may be found, not in points, but on two surfaces, or two portions of given surfaces. This happens in experiments with the ellipsoidal swelling or centre of the tube of Geissler. This ellipsoid being placed on the armatures of a powerful electro-magnet, so that its axis be perpendicular to the line of the poles, there is necessarily formed in its interior, at a distance from the two electrodes, a luminous vault, presenting the form of a magnetic surface, terminating in all its parts in the internal side of the glass. Plücker seems to have found the complete explanation of this portion of the curious inquiry. This memoir is in *Poggendorff*, vol. civ.

IV. The important question remains, however, what is the cause of these stratifications? We have been able to describe the main phenomena; but nothing in the previous part of this paper tends to explain why they exist at all. Several speculations, indeed, have been hazarded, but none of them grasp the subject;—nor, perhaps, are the phenomena themselves fully or adequately known. At a comparatively early period, for instance, after Grove's discovery, the idea of *interference* was not unnaturally suggested,—an idea peremptorily negatived by Gassiot, who artificially produced "*interferences*" of two currents, without evolving any analogous strise. M. Morren of Marseilles is probably not far from the truth, when he writes—"J'attribue la stratification a une variation dans l'intensité de la tension de l'électricité qui circule, mais surtout a l'insuffisance des corps conductives gazeux, a travers desquels le courant passe;" but he is quite in error when he imagines the phenomena represented by the forms of brushes, &c., received on a piece of glass, of lateral disruptions from a strong current, forced

along a wire lying on the face of the glass. Rigorously examined, there is no resemblance whatever between these explosion-pictures and the electric stratification. Mr. Grove, to whose lightest opinions every consideration is due, has recently been inclined to attribute the phenomenon to the interaction of two discharges from the induction coil—one of the currents being the *true induction current*, and the other an *extra current*. In Dr. Robinson's more recent paper, however, this solution appears satisfactorily disposed of (*Philosophical Magazine*, April, 1859), so that, in so far as this goes, we are as much in the dark as ever. A recent note, by MM. Quet and Seguin, seems to have advanced one step. They have modified the original conception of M. Morren, and given experimental proof of its reality, as thus modified. An attenuated gas being simply a flexible or very mobile conductor, they have rightly asked, whether similar stratifications might not be produced experimentally, by directing the current through imperfect and mobile conductors, of a sort that would leave traces of the passage of the current in a visible form? They took accordingly a plate of glass, narrow and of some length, and having strewed it over with charcoal dust, they brought an induced current to act at its extremities. After the discharge had continued for some time, the dust arranged itself in *transversal lines*, separated by a small interval,—presenting an appearance entirely analogous to the stratifications of the Electrical Egg. Precisely the same appearances were evolved in the midst of a dark or smoky flame, such as that from the burning oil of turpentine, when the discharge passed through it. Their conclusion is, that these stratifications may be explained by the propagation of electricity through the conducting dust, causing a repulsion between the particles of the dust. "The foregoing experiments," they say, "prove that gases electrized are subject to electric attractions and repulsions, that imperfectly conducting and mobile media are disposed by these electric influences into beds of different densities, and that this disposition, giving rise to differences in tension, originates the luminous strata." The electric influences passing through an attenuated gas thus originate condensed and rarer beds: "that the dilated beds conducting electricity in the same way as is done by the metallic particles in the common experiment of the illuminated sheet,—the two fluids acquire on both sides of the more imperfectly conducting beds such a tension as enables electricity to traverse them under the form of a discharge, and therefore to illuminate them."—It is easy to see, that supposing MM. Quet and Seguin to be correct, they have done little more than produce analogous appearances. One thing alone is plain:—setting aside all specialities and variations, we have before us the fact, that the current passes through these in-

perfect and mobile conductors in such a way that successive zones become charged up to the point of disruption: so that we are forced on the difficult inquiry,—in what manner does the “mode of motion” which we term *Electricity* propagate itself through such conductors? perhaps also on the still more general one,—in what manner does this mode pass into that other mode of motion, which we term *Light*? Inquiries like these are rapidly coming within our reach; and while indulging in all Dr. Robinson’s hopes, we agree with him, that the first essential step must be a thorough “mathematical investigation of a current’s motion through an imperfect conductor.”

Electrical Images. See IMAGES.

Electrical Machine. The electrical machine consists of a circular glass plate from $\frac{1}{4}$ to $\frac{1}{2}$ of an inch in thickness, and the diameter of which may vary at pleasure. The plate is traversed at its centre by a metallic axis fixed solidly to the glass. This axis rests on two wooden supports fixed vertically; and is so placed that the glass plate is situated between the two supports, and at an equal distance from either. A handle fixed on the extremity of the axis serves to give a rotatory motion to the plate. The greater part of the handle is made of glass or some very bad conductor of the electric influence.

Two pairs of horse-hair cushions are made to clamp, the one the upper, and the other the lower part of the plate; cushions which by their elasticity exert a considerable pressure on the plate. To facilitate the liberation of electricity, the surface of the leather of each cushion is coated with an amalgam of zinc, or of mosaic gold (deuto-sulphuret of tin). Finally, the vitreous electricity developed on turning round the glass plate is collected by cylindrical conductors generally of brass, that, with their ends near the plate, are placed horizontally and supported on glass pillars attached to the table.—In this machine, the cushions communicate with the ground by means of the wooden supports and the table: sometimes a metallic chain is added to facilitate this communication: thus the negative electricity which they acquire—as the positive is given off to the conductor—passes away as it is liberated: should

we wish to collect it, the cushions themselves must be insulated by glass supports, and the construction of the machine slightly modified. Both electricities, or any one of them, may thus be manifested and collected by means of this machine. Formerly, in the construction of electrical machines, glass muffs or cylinders were employed, instead of circular plates; but although very powerful machines of the cylindrical sort have been constructed, the disc or plate is now almost always used.—The power of the plate machine—other things being equal—depends on the size of the plate: the largest ever made is the gigantic one at present in the Panopticon in Leicester Square, London, constructed after the designs of Mr. Marmaduke Clarke, of a plate whose diameter is about *eleven feet*! It can produce effects rivalling those of thunder.—The electricity given by the machine—as contradistinguished from that of the battery—is always in a state of high tension.

Electrical Machine—Armstrong’s. Hydro-Electric Machine.—A most powerful method of obtaining electricity in a state of high tension; discovered accidentally by a workman who discerned electric sparks emitted by a locomotive engine; reduced to practice by Mr. Armstrong; and subsequently thoroughly investigated by Faraday. The electric excitation taking effect when steam at a high temperature issues from a tube attached to the steam boiler, it was at first imagined that the singular result is in somehow connected with the process of evaporation or vaporization; but Mr. Faraday, by a series of perfectly satisfactory experiments, has shown that this change of state, has nothing to do with the matter. It is purely a case of electricity created by *friction*: and the friction is the violent rubbing of particles of water (carried rapidly forward by the force of the steam) against the orifice through which they issue. *Dry steam* will not produce any effect; nor do effects follow when water is mixed with any saline or other material that converts it into a good conductor. The particles of other liquids carried forward with the same force, produce in every case the effects which we should expect from them employed as *rubbers*. Dry air produces no effect; but *powders* of different substances, carried by a stream of dry air, also evolve the electricity natural to them under friction.—This simple explanation grasps the entire case; and suggests many forms of apparatus. Mr. Armstrong has made a very effective one—of an insulated steam boiler, with openings conveniently placed, through which moist steam, or steam carrying particles of pure water, may rush, with whatever violence is desired. The mouthpieces of the issue pipes are usually of wood.

Electrical Machine—Rumker’s. See INDUCTIVE ELECTRICAL MACHINE.

Electricity. In some of the ancient Greek writings it is mentioned as a then well known

fact, that when a piece of amber is subjected to vigorous friction, it acquires the temporary power of attracting light bodies from a distance. A similar property appears to have been observed by the ancients in one or more bodies besides amber; but the fact of such a peculiar development of force by friction is stated in the ancient writings in special connection with the latter substance, probably because the property was first observed in that substance and most generally known in connection with it. The Greek name of amber is *Electron*, and hence the term *Electricity*, a term that has been universally adopted as the name of that peculiar agency first observed in rubbed amber, and as the name also of the science of that agency. The great use of the name of a science is to indicate clearly the subject matter of the science; and in this respect the term *electricity* is perhaps as good as any other that could be devised even in the present state of knowledge. But the name has a great additional interest to the student of nature from its historical connections: it forms, in fact, a permanent memorial of the smallness of those beginnings from which this, the most extensive of the physical sciences, has sprung. We cannot attempt to give in this article even the briefest sketch of the progress of electric discovery. We may only observe that *Electricity* is a science of purely modern growth. Down indeed till the 17th century, the science made no real advance beyond the fundamental fact already stated, if we except a slight extension of the list of substances excitable in the same way as amber. But since the appearance of Gilbert's work on magnetism in the year 1600 till the present day, the phenomena of electricity have been studied very closely and laboriously by many eminent philosophers. In consequence of their unwearied exertions, directed as they have been by the sound inductive spirit of the modern philosophy, discovery has followed discovery in rapid succession; new and wide fields of inquiry have been successively opened up, while the older fields were yet evidently unexplored; and powerful means of further discovery have been permanently secured from time to time by the invention of new scientific instruments and the perfecting of the old. So that in the present day, the science of electricity contains a very large and varied body of most interesting physical knowledge, and is replete also with clear illustrations of the principles, methods, and resources of the inductive philosophy. It will not be out of place to make now a brief statement or two in recommendation of the study of this branch of science. And first, if we look into the records of the sciences, we observe a very peculiar feature in the case of electricity. On several occasions in the course of discovery, this science has spoken for itself to the world as no other has. By the marvellous nature of its results it has forced the attention even of the most ignorant, and roused

the admiration of all. Witness the simultaneous discoveries of the Leyden Phial and the Electric shock. Witness also the astonishing achievement of Franklin, in drawing down a charge of lightning from a thunder-cloud, taking it home with him, and experimenting upon it at his leisure. After such things, *Electricity* must have taken its place among the most popular and the best known of the sciences. Further, if we look to the practical applications of knowledge, electricity holds in this respect a very high place in fact, and a still higher in legitimate expectation. The Lightning-Conductor, so valuable as a means of preserving life and property; the Electric Telegraph, so widely employed already for the purpose of express; and the Electro-Plating processes, so useful in the arts, and so conducive to the comforts and elegancies of life: these are instances of what electricity has done, and earnest of what it may have yet to do. So that in the practical view electricity takes its place among the most valuable of the sciences. But in conclusion, we cannot see the full importance of this branch of physical science, till we take a liberal and comprehensive view of it, as one section of the great study of nature. And in this respect, the singular importance of electricity appears chiefly in the closeness and variety of those relations that have been discovered between the electric agency and the other forces of nature. It is now clearly established that *Electricity* is intimately connected with Magnetism, Light, Heat, the chemical forces, and the molecular forces; and that, in fact, we can detect the presence of electricity either as cause or effect in almost every physical action which is accessible to us. By the discovery of such relations the varied phenomena of nature are being drawn together towards a great central theory; and if the hopes of philosophers are to be realized in regard to one science of the natural forces that will embrace all the branches of mechanical and chemical knowledge under a few common principles, there can be no doubt that electricity will be the principal guide to such a science, and will hold the principal place in it. These remarks are sufficient for our present purpose; and we may now attempt a brief statement of the simpler phenomena and laws of electricity.

In treatises upon this subject, the development of an attractive power in amber and other bodies by friction is usually the fact first mentioned; and this not merely because it was the fact first discovered in electricity, but because it is in itself one of the simplest facts, and the most easily brought out in experiment. We can develop the attractive power very easily by means of a rod or tube of common glass. Let the rod be well dried, which may be insured by heating it; and let it then be vigorously rubbed with a dry silk handkerchief. This is all that is necessary for exciting

or electrifying the rod of glass. When the experiment succeeds best, a slight crackling may be heard during the progress of the friction. But even when this effect is not produced, the electric state of the glass may be made manifest by its mechanical actions; for if the excited part of the rod be brought near to any very light bodies, such as bits of paper or barbs of feathers, the bodies will fly through the air from a distance, and attach themselves to the surface of the rod. The attractive power of the glass disappears very soon, but it may be restored by a repetition of the friction. To manifest this and other mechanical actions of electrified bodies in a convenient way, we make use of a simple apparatus, called the Electric Pendulum, which is shown in the adjoined figure. In this form

Fig. 1.

of electroscope, the light body employed is generally a pith ball, one-fifth or one-fourth of an inch in diameter; and it is attached by a thread or fine wire to a fixed support, which is bent into such a form as not to interfere with considerable movements of the ball. We shall suppose that the thread is a film of raw silk, and that the support is of glass. With this simple apparatus we can easily manifest some of the elementary laws of the electric forces. A glass rod is excited by friction, and brought near the ball of the pendulum in the same horizontal plane or nearly so: the force is immediately made evident by the attraction of the ball, and the consequent displacement of the thread from the vertical position. If the excited rod be withdrawn to a greater distance from the pendulum, the thread returns towards its vertical position; showing that the electric attraction diminishes as the distance between the bodies is augmented. If a dry pane of glass be interposed between the excited rod and the ball of the pendulum, there is no change observed in the mechanical action of the rod upon the ball; showing that the electric attraction can be transmitted through solid bodies as well as through air. Further, if the excited rod be brought so near as to attract the pith ball up to contact with itself, we observe that, after contact for an instant, the ball falls away from the rod into its original position, and even beyond it; and if the rod be now made to approach the ball, the thread again moves from the vertical position, but in such a direction as to indicate that the electric force after contact is repulsive. It will be easy to observe in this case that the pith ball itself is now charged or permanently excited; for if the rod be altogether withdrawn, the ball will now act mechanically upon light bodies brought near to it, in precisely the same way as it was itself acted on by the excited rod. We see, therefore, that when the electric affection has been de-

veloped in glass by friction, it can be transferred from the glass to another body by mere contact; and it is this fact, as we shall soon find, which explains the change of the electric force from attraction before contact to repulsion after contact. A few additional statements may be here made in regard to the transference of electricity from an excited or charged body to another body. And first it may be observed, that contact between the bodies is not necessary. An excited glass rod will part with more or less of its charge to another body, such as a piece of metal, when it is brought very near it, without actually touching it. In this case the electricity gives indications of its passage by a slight spark between the bodies, accompanied by a snapping sound, phenomena which are identical in their nature with the thunder and lightning of the atmosphere. As electricity may be transferred from an excited glass rod to another body, so it may be transferred from the latter to a third body, either by contact or spark. We are therefore able to conduct a charge from one body to another *through* an intermediate body. Thus, if a long metallic wire be suspended by threads of silk, and if one end of the wire be electrified, a pith ball suspended in contact with the other end of the wire will be immediately repelled by it; showing that the electricity has been conducted along the wire, and that part of it has been transferred to the pith ball. Here, however, we meet with a remarkable class of distinctions among bodies. If a rod of glass, or a rope of silk, had been used instead of the wire in the last experiment, no charge would have been transmitted to the pith ball. Glass and silk are therefore called nonconductors, while the metals and other bodies that act similarly are called conductors. For further information upon this point see the article upon CONDUCTION. The facts now mentioned, with others of the same class, admit of important experimental applications in the *Insulation* of conductors. Generally a conductor is insulated when it is placed in such relations to surrounding matter that a charge bestowed upon the conductor shall be retained by it. Arrangements to this effect are of essential importance in a large class of electrical experiments; and they are very simple, both in principle and practice. We insulate a body by enveloping it upon all sides with nonconducting matter. The atmospheric air is a good nonconductor, and we therefore insulate a conductor when we suspend it in air by a nonconducting thread, or support it in air by a nonconducting rod. But the insulation in such cases will be rendered very imperfect by the presence of moisture to any great extent in the air; for water is a very good conductor, both as a liquid and as a vapour. For details in regard to insulation, and the dissipation of charges from electrified conductors see the article upon INSULATION. We have hitherto considered only one case

of electrical excitation, that of glass when rubbed with silk. We may now take up another case equally simple, that of a stick of sealing wax when rubbed with woollen cloth. The two cases taken together will give a simple proof of the fundamental fact, that there are two distinct species of electricity. It has been already stated, that when the insulated ball of an electric pendulum has been attracted up to contact with an excited rod of glass, it receives a charge of electricity and is repelled by the rod, and conducts itself thereafter in the same way as the rod itself does, attracting generally those bodies that the rod would attract, and repelling those that the rod would repel. Excited sealing wax gives precisely the same results. But a new effect is observed when we charge the ball of the pendulum by contact with glass, and bring an excited stick of wax near to it: the ball in fact is attracted by the wax, instead of being repelled as it would be by excited glass. A similarly attractive action is exerted by excited glass upon a ball that has been previously charged by contact with excited wax. The electricities developed in the glass and in the wax must be distinct from each other, since they thus exert contrary actions in similar circumstances, each attracting a body that would be repelled by the other. The one electricity is called the Vitreous or Positive, and the other the Resinous or Negative. In another instructive form of the above experiment, we charge one pair of insulated pith balls from excited glass, and another pair from excited wax, and observe their mutual actions when brought near each other. We find thus, that similarly charged bodies are mutually repelled, while those dissimilarly charged are mutually attracted.—From the law of the mechanical actions now stated, we derive a simple method of determining the species of electricity with which a body is charged in any actual case. Let the insulated ball of an electric pendulum be charged with a *known* electricity, either Vitreous or Resinous; and let the body which we wish to examine be brought up from a distance towards the ball. Then if the body repel the ball, it has a charge similar to that of the ball; and if it attract the ball, it is either dissimilarly charged or not properly charged at all. The former action, that is, the repulsive, may be depended upon in all cases as indicating the existence of a charge upon the body similar to that upon the ball. We say, therefore, if a body repel the ball when vitreously electrified, that the body is also vitreously electrified. Such a statement cannot be understood in its full and proper import without the generalization of our notions in relation to the *two electricities*. We have defined the Vitreous and Resinous electricities, as those which are derived from the excitation of glass and sealing wax by friction with silk and wool respectively; and we suppose that the test-ball of the pendulum is electrified from either of these

sources. If we now obtain, by any means, a conductor which repels the ball, we say that this conductor and the ball are similarly electrified, that is, both vitreously, or both resinously. And by this we mean, not merely that the ball is mechanically affected by the new charge in the same way as it would have been affected by a *Vitreous* or *Resinous* charge, according to the original and restricted sense of these terms; but also, that the new charge, when once identified so far, say with what we have called the Vitreous Electricity, by the simple determination of its mechanical action upon the ball of the pendulum, may be now identified with that electricity in all respects. In other terms, every actual charge is identifiable in all its properties, either with what we have called the Vitreous or with what we have called the Resinous electricity. And this, of course, is the only adequate reason for the unqualified extension of the terms Vitreous and Resinous to any other charges besides those which have been obtained by the excitation of glass and sealing wax. The two electricities, as already stated, are called also Positive and Negative, the Negative being the Resinous.—In these introductory remarks, there is only another point that we shall refer to, that is, the effect of the mutual contact of two oppositely electrified conductors. The best way of exhibiting the effect is to allow the two conductors, say two pith balls, to attract one another up to mutual contact. At the instant of contact there is an evident modification of the electric forces. The two bodies fall away from each other; and thereafter they either repel one another, or exert no mutual action at all. The opposite electricities appear to have united and destroyed each other wholly or partially at the time of contact. A similar annihilation of the electric forces may be effected by bringing the two bodies into contact with a third conductor. The conductor opens a path to the two charges, and fulfils the function of a mutual contact of the bodies. These facts, along with those already stated under the head of Conduction, will give an elementary conception of *Electricity in Motion*. Contrasted with other facts, they suggest a simple, though not a perfect division of electric science into two branches, Electro-Statics and Electro-Dynamics. In the former of these branches we study the various phenomena that are presented by *stationary charges* of electricity; and in connection with these phenomena we study also the laws of the development and disappearance of charges, or in other terms, the laws of *excitation* and *discharge*. In Electro-Dynamics, which is now much the more extensive branch of the science, we consider the phenomena of electricity in motion, or the laws of discharge in general, and more especially the laws of continuous discharge or of electric currents; and here also we meet a special and important class of facts in regard to the excitation of electricity. In the present article we

shall take up the principal points of Electro-Statics as briefly as possible, referring the reader to various subordinate articles for additional information.

1. Of *Excitation* we have had already two instances, in the friction of glass with silk, and in that of resin with wool or fur. We have detected and compared the charges which are developed in those cases upon the glass and the resin, and we have taken them as the standard representatives of *the two electricities*; but we have not yet examined the electric state of the rubber in either case. The examination may be simply effected by wrapping a silk handkerchief round a non-conducting rod, and then rubbing it with a tube of glass. By this action the glass will be positively electrified, as we know; and if the silk be examined by the action of the electric pendulum, or other similar means, it is found to be also electrified, but negatively. A similar examination of the second case would show, that when resin is negatively electrified by friction, its rubber is also electrified, but positively. These facts are suggestive of a law of excitation, which is found to be universal, that when one of the electricities is evolved by any means, the other is evolved by the same means along with it. Extending now our inquiry upon excitation by friction to other substances besides glass and resin, and their rubbers, we can hardly find any couple of bodies that are incapable of being electrified by a properly managed friction of the one against the other. In the infancy of electric science, many bodies, including all the metals, were understood to be unexcitable by friction, and they were therefore called *Anelectrics* or *Nonelectrics*, in distinction from the excitable class, which were called *Electrics* or *Idioelectrics*. This was prior to the discovery of the electric conductive powers of bodies—a discovery that completely explained the appearance of unexcitability presented by the metals and some other substances. If a rod of iron, for example, be held in the hand, and rubbed with woollen cloth or any other substance, it will remain perfectly unexcited. But, remembering the high conductive powers of the metal, we explain the absence of charge after friction, in this case, by supposing that the electricity, as soon as it is developed, is conducted away from the metal, through the hand and body of the operator, into the ground. To test the truth of this explanation, we have only to insulate the metal in relation to the hand that excites it. We may attach it firmly, for instance, to a glass handle, and hold it by the handle. In these circumstances, the metal conducts itself under friction as an *Idioelectric*, receiving a sensible charge, and retaining it for some time, just as a rod of glass would. By the adoption of precautions similar to the above, in other cases that require it, we find that all bodies, except the gases, appear to be capable of excitation by friction, though in very different

degrees. There is one class of cases, however, that presents great difficulty—that is, when the two bodies employed are both good conductors. It is only in special forms of experiment that we can obtain any sensible charge in such cases; and this might have been expected. Still, though we cannot obtain a sensible charge, we have satisfactory evidence otherwise of the development of the electricities by friction. In extending the assertion of excitability, as we have done, to all bodies except the gases, we have included, of course, the liquids. These are excitable, both by mutual friction and by friction against solids. Of the latter case, we have a good instance in Armstrong's Hydro-Electric Machine, in which the *rubber* is water in the form of small drops. The drops are suspended in a rapid current of steam, and are driven along with it through an irregular channel of wood, against the sides and projections of which they are powerfully dashed and rubbed by the force of the steam. By the friction thus accomplished, both the wood and the steam are electrified, and the electricities are easily collected. The Hydro-electric machine appears to be the most powerful instrument of excitation that we yet possess. The simple apparatus represented in the adjacent figure may be usefully employed in illustration of the laws of excitation. The discs are formed of glass, wood, resin, or any other substances, the same or different, and they are both furnished with insulating handles. We can change the nature of either of the rubbed surfaces at pleasure, by covering the face of one of the discs firmly with different kinds of cloth or paper, or by coating it with varnish or other similar substances. In every variety of experiment thus obtained, we find that when, by the mutual friction of the discs, one of them is positively electrified, the other is at the same time negatively electrified. We find also that the two opposite charges, which are simultaneously developed, are in every case equal to each other. This equality we infer from the perfect equality of the mechanical actions of the discs upon the insulated ball of a pendulum, and still more surely from the neutralization of the electric actions of the discs upon all external bodies when the excited faces are placed in mutual contact. We find also that the quantities of the opposite electricities which are developed in any case of excitation, leave no free electricity when they unite in discharge; and hence we derive the important law, which is found to be universal, that the quantities of opposite electricities which are neutralized in discharge are equal to each other.—When two bodies, then, are subjected to mutual friction, they are *oppositely* and *equally* electrified. But, can we certainly foresee which body of a given couple shall be positively electri-

Fig. 2.

fied, and which negatively? This question leads us to a branch of the subject that has been very thoroughly studied. And first, it appears that the determination of a particular electricity—say the positive—to one element rather than the other of a rubbed couple is dependent, to a great extent, upon the *nature of the bodies*. We have had proofs of this fact already, in glass and silk as one couple, and in resin and woollen cloth as another. In these and some other instances it is barely if at all possible, to change the final disposition of the electricities upon the two bodies by any variation of the circumstances of the experiment. If we now form a number of couples, and observe the positive and negative body in each, it will appear that the relation between the elements of a couple, as positive and negative, is still preserved when the bodies are coupled separately with other bodies. It is evident, therefore, that bodies may be tabulated in the order of their positive, or negative tendencies, when subjected to friction; and such tables are accordingly given in the elementary works on Electricity. If any two bodies contained in such a table be rubbed against each other, the one which is farthest on, say in the table, is always negatively electrified. The following table is one that is generally adopted:—Fur of a cat, polished glass, woollen cloth, feathers, wood, paper, silk, gum-lac, rough glass. It is not to be supposed, however, that the facts will constantly come out in accordance with the arrangement of bodies now indicated. Very slight changes in the circumstances of the experiment are often sufficient for the inversion of the electricities on the two bodies after friction. And we have now to notice, therefore, some of the circumstances, besides the nature of the rubbed bodies, which affect the determination of a particular electricity to a particular element of the couple. The *state of the surfaces* of the couple is one of these circumstances. Thus, polished glass is a highly positive body, while rough glass is highly negative. Two ribbons, again, which consist of the same stuff, but which are of different colours—the one white and the other black—are strongly electrified by mutual friction—the black being always negative. These are instances of the influence which the state of the rubbed surface exerts upon the phenomena of excitation, and they are cases of what appears to be a universal law—that, by roughening or blackening the surface of a body, we render the body more highly negative—that is, more susceptible of being negatively electrified by friction against other bodies. The *proportion of the parts rubbed* of the two surfaces is another important element. Two ribbons, for example, are electrified by mutual friction, though they are similar to each other in every respect, when the one is rubbed longitudinally across the other. The latter is always negatively electrified; and, in general, when the frictional action is concentrated more upon one of the surfaces than upon the other, the ten-

dency of the former surface, in virtue of the unequal distribution of the friction, is always negative. Another important circumstance is the relation of the two bodies rubbed in regard to *temperature*. When we subject two perfectly similar bodies to mutual friction symmetrically there is no excitation produced; but the result is different if one of the bodies has been heated before the friction; the bodies, in fact, are now electrified after friction, the heated body being negative. We find, also, as we should expect, that if we take any couple of electrics, and heat the positive body before friction, the amount of electricity now excited by a given amount of friction is less than formerly; the positive body, in fact, has become more negative or less positive by the increase of its temperature, and the couple has been to that extent weakened. And in many cases, where the positive body can stand a sufficient increase of temperature, we are able actually, by changing the temperature, to reverse the relation of the two bodies as positive and negative, and to obtain considerable charges in the other direction. While we restrict ourselves to charges of sensitive intensity, Friction is, practically, the most important cause of excitation; but there are two other causes—pressure and heat—that may not be altogether overlooked. Two bodies may be sensibly electrified by a mere pressure of the one against the other. This is true of the most of bodies, but the phenomena are presented very remarkably by some crystalline and laminated structures. Calcareous spar, arragonite, mica, topaz, and some other bodies, are very sensibly electrified by pressure for an instant between the fingers, and the electricity thus developed is retained by the bodies in sensible intensity for hours, and even sometimes for several days. In the case of excitation by pressure, as in that due to friction, the bodies of any couple have definite and pretty constant relations to each other, as the one positive and the other negative, and these relations are affected in the same way in both cases by an unequal distribution of heat between the bodies, and by a difference of polish in the surfaces. Considering the important part that heat plays in excitation, we might expect that the agency of heat alone would be sufficient, in favourable circumstances, for the development of electricity, and this is actually found to be the case. The electrifying action of heat has been specially studied, as exhibited by the tourmaline—a crystal that we obtain chiefly from Ceylon. When the temperature of a tourmaline is either increasing or diminishing within two definite limits, the crystal is found to be electrified positively at one extremity, and negatively at the other. When the heating or the cooling is effected rapidly, the intensity of the electricities evolved is very considerable, as appears by the attraction of light bodies from a distance to the surface of the crystal. If a tourmaline has been retained for some time at any constant tem-

perature, it gives no electric signs; but when we add or subtract heat, the electric poles begin immediately to appear, and remain active till we reach either of the limiting temperatures. It is a remarkable fact that the disposition of poles for increasing temperatures is contrary to that for diminishing temperatures; so that, if the tourmaline is regularly heated to a certain point, and then regularly cooled, the electricities first disappear at the extreme temperature, or shortly after it, and finally reappear at the ends of the crystal, having changed places. There are many crystals which are now known to possess electric properties analogous to those of the tourmaline; but we will not enter further into the subject at present.—In electrical experiment it is very frequently necessary to obtain powerful charges, and the best means to this effect have been conjoined in that important instrument, the Electric Machine. The most common form of the instrument is that represented in the article ELECTRICAL MACHINE. It consists of several parts, which we may describe in connection with their separate functions of excitation, collection, and insulation. The means of excitation are—first, a glass plate which is turned round a fixed horizontal axis by means of a handle attached to it; and secondly, a pair of rubbers which are kept in contact with the two surfaces of the plate above its centre, and a pair similarly disposed below the centre. The rubbers consist of leathern surfaces coated with an amalgam, and both pairs are attached to the vertical support of the axle of the plate, and, by means of interposed cushions, are pressed constantly against the moving surfaces of the glass. When the plate is well dried, and the amalgam of the rubbers fresh, the turning of the plate will powerfully excite both the glass and the cushions, the former positively. The next part of the apparatus is that by which we collect and accumulate the electricity thus excited. Two conducting rods, in the form of hollow metallic cylinders, are fixed in positions parallel to the axle, and with their ends near the extremities of the horizontal diameter of the plate. From each of these ends proceed two metallic arms towards the centre of the plate, on opposite sides of the plate, and close to its surface. The surfaces of the arms which face the plate are furnished with points, which favour the desired effect, as we shall afterwards see, although they are not necessary to it. It is evident that when we work the machine by turning the plate, the part of the glass surface which has been excited by friction against either of the rubbers comes immediately under the influence of the metallic arms, and parts with its electricity to the conducting cylinders. In the machine represented in the figure, the electricity excited upon the rubber is conducted away into the ground, as its accumulation on the rubbers would put a stop to the process of excitation; but in other forms of the machine the two electricities are both collected. Further, the two

cylinders are connected by a rod of metal at their ends, remote from the plate, and the one piece of conducting matter thus formed is called the Prime Conductor of the machine. The third part of the apparatus is for insulation, or for effecting the retention of the charge upon the Prime Conductor. This function is fulfilled by the insulating power of the glass rods that support the Prime Conductor. The apparatus now described is a very important instrument of science. It enables us to exhibit the properties of stationary charges in a much more convenient and clearer manner than we could do by the elementary methods of excitation, with glass rods or sticks of wax; but it is especially valuable in experiments upon the communication of electricity, and upon the various effects of discharge.

2. We may now attend to the phenomena of *Induction*. In the adjacent figure, B represents an *insulated* metallic cylinder, which has several pairs of pith balls, attached by conducting threads to different points of its surface. The

Fig. 2.

cylinder being uncharged, let an electrified ball, A, be brought up towards one of its extremities. We know that if the distance between B and A be sufficiently small, the electricity of A will be partly transferred to B, by discharge through the air. But, before the distance has been thus far diminished, there is a sensible development of electricity in B. The pith balls of several pairs in the above arrangement are seen to diverge from one another, and the divergence increases as A approaches—showing that the pith balls and the cylinder to which they are attached are electrified, without discharge, by the mere neighbourhood of A. In this simple experiment it is observed, further, that the electricity is developed in greatest intensity at the extremities of B, and that there is no sensible development about the middle of the cylinder. If the electrified ball, A, be now withdrawn, the pith balls collapse, and the cylinder loses all traces of charge. Here then we have a method of developing electricity which is in remarkable contrast with the two methods already noticed—excitation and communication; for the charges developed by the latter methods in insulated conductors are, in every case, persistent or self-sustaining, when the originating agency has been suspended. This remarkable property of the charges *induced* in insulated conductors is explained, as we might have expected, by the fact that the inductive action of A develops in B, not merely one electricity, but *equal* quantities of the *two* electricities. This fact is easily proved by observation. Let

an insulated pith ball be charged by contact with A, and let it be brought near the balls of B when they are diverging under the inductive action of A. It will be seen that the pith ball attracts those balls of B which are at the extremity next to A, and repels those which are farthest from A. The cylinder is therefore oppositely electrified at its two extremities by the influence of A, and the charge similar to that upon A is at the extremity remote from A. The two electricities appear also, as already stated, to diminish in intensity as we proceed from the extremities of B towards the middle, where there are no electric signs at all. These facts are equally well proved without the attachment of pith balls or other electroscopes to the cylinder. By means of the Proof Plane—a very small metallic disc attached to a long insulating handle—we can draw small charges from different parts of the surface of B by contact, and then we can test the species and intensity of the charge upon the Proof Plane by means of an electroscope. It can be proved further, by direct observation, that the opposite charges developed in B are equal to each other; but this appears to be sufficiently proved by the fact, that when A is withdrawn, the two charges on B are mutually destroyed. Suppose now, that while B is under the inductive influence of A, we uninsulate B, or connect it with the ground, the charge upon B that is remote from A, or similar to that upon A, immediately disappears; and if, after this, we first insulate B, and then withdraw the body A, we find that B is charged, and with an electricity opposite to that upon A. This result may be explained by a reference to our original arrangement of pith balls in connection with B; for when B is uninsulated, it is connected with the conducting mass of the earth, just as one of the pith balls is connected in the original arrangement with the mass B. And, more particularly, the relation between B, when uninsulated, and the immensely greater conducting body of the earth, is precisely similar to the relation between B when insulated, and the smaller conducting mass of a pith ball attached to the end of B that is next to A; so that, as the pith ball will be charged with one electricity in the latter case, the cylinder B will be similarly charged in the former, and will retain its charge when it is detached from the earth by insulation.—Hitherto the charge upon A has been considered as merely acting inductively upon B; but this is not an adequate view of the electric relations of the two bodies. The inducing charge is itself affected inductively by the electricity which it develops and sustains in B. It is affected, not in the way of loss or gain of electricity upon the whole, but in the way of distribution. If we examine different points of the surface of A by means of a proof plane and an electrometer, we find that the intensity of the electricity on the parts of the surface which are next to B is much greater than

on the parts remote; so that, as the charge of A attracts the opposite electricity in B towards A, the latter attracts the opposite charge of A towards B. If we now consider the case of two insulated conductors, which are both electrified, and brought near to each other, we can express their mutual inductive actions in these terms—that the opposite electricities are mutually attracted, and the similar electricities mutually repelled. Referring to our original arrangement of the ball A and the cylinder B, suppose the two bodies to be insulated and similarly electrified. Then, if A be brought up towards one extremity of B, the pith balls at that extremity will collapse, and those at the other extremity will have their divergence increased—showing that the electricity of A repels the similar electricity of the other body. If B had been oppositely electrified, its charge would have been attracted or determined with greater intensity towards the parts of the surface adjacent to A. And in both cases, and indeed in all cases, the action of the charge of B upon A is precisely similar to that of the charge of A upon B. It may be now easily understood that an insulated conductor which is electrified, say positively, may have a distribution of negative electricity induced over a certain portion of its surface, and this whether the inducing charge be positive or negative. Suppose that the inducing charge is positive, and much greater than the charge upon the body examined, then the first effect of induction will be a diminution of the intensity upon the parts of the body adjacent to the inducing charge, with a corresponding increase of intensity on the parts remote. As the bodies approximate this effect increases, until the positive electricity is entirely repelled from one part of the surface; and upon this part the negative electricity will be elicited if the distance between the bodies be still diminished.—The precise consideration of the laws of induction cannot be here attempted; but it may be stated that, in every attainable system of inductive actions, the two electricities appear to conduct themselves as two material fluids, which are self-repulsive and mutually attractive with forces, varying inversely as the square of the distance, and directly as the product of the fluid masses. And we include in this statement the case of uncharged conductors by assuming, as the phenomena compel us to assume, that every insulated conductor possesses an unlimited fund of the two electricities; and that these electricities, though mutually neutralized and inactive, are yet subject to the attractive and repulsive actions of induction, just as free charges are. Suppose now that we have a system of conductors placed near one another, and that one or more are electrified. The whole system will immediately fall into a particular electric state. Each conductor will have a stationary distribution of one or both electricities upon its surface—a distribution sustained by the inductive actions

of all the charges, original and induced, throughout the system. And it is evident, from the above statement of the law of induction, that the question of the distribution of electricity in such a system is just a question of equilibrium of fluids, which are subjected to definite forces, attractive and repulsive. This forms one of the principal subjects of investigation in the Mathematical Theory of Electricity. The adjacent diagram represents a simple experimental arrangement which we owe to Faraday, and which is of great value for the simplicity and clearness with which it brings out some important principles of inductive action. The vessel A is an

Fig. 4

insulated pewter ice-pail, about a foot in height. It is connected by a wire with a delicate electrometer, E . C is a metallic ball, insulated by a silk thread three or four feet in length. If the ball, C , be charged and let down into A , as in the figure, the electrometer, E , will at once diverge with a charge similar to that upon C . This effect the reader will understand from what precedes. If C be positively charged, the negative electricity will be attracted to the interior surface of A , and the positive will be repelled to the exterior surface, and still more strongly to the remote body, E . As the ball enters A , the divergence of the electrometer will increase till C is several inches below the edge of the vessel, and it will then remain constant for all lower positions of C . From this we infer, that in those lower positions the entire inductive action of the ball's charge is exerted upon the inner surface of A , while, in the higher positions, part of that action is spent upon internal conduction. Of course, we here speak of the inductive action as it is *sensibly manifested* by its effect upon the electrometer. It may now be understood that a charged conductor, placed in the middle of a large room, and apart from other conductors, will yet perform its inductive function as completely as if it were in the circumstances of the ball, C ; for the place of A will be supplied by the walls of the room, which will therefore be electrified with a charge opposite to that of the conductor, and equal to it, as we shall see immediately. When the ball C is suspended in the vessel at a sufficient distance to prevent discharge, the vessel A , and its attached electrometer, have no excess of either electricity. This may be proved by withdrawing C from the vessel, when E will collapse perfectly if the apparatus is in good order. When C is suspended in the vessel, the divergence of E is therefore a measure of the charge induced upon the inner surface of A ; and if C touch the interior surface of A , and communicate its charge to the vessel and the electrometer, the divergence of E will be a measure of the original charge of the ball.

But the divergence of E is absolutely unchanged by internal discharge between C and A ; and hence Faraday infers, from direct experiment, that "the electricity induced by C and the electricity in C are accurately equal in amount and power." For developments upon this subject, into which we cannot enter, the reader is referred to *Faraday's Experimental Researches*, vol. ii., page 280. The most important additions that have been made to Electro-Statics in recent times are contained in the discoveries of Faraday, and in his peculiar views, with regard to the nature of inductive action. For information upon these points, consult the article on INDUCTION; see also ELECTROSCOPE and ELECTROPHORUS, for simple applications of the principles above stated.

3. We may now consider the laws of the *Electric Forces*. We have seen that similarly charged bodies repel one another, while those oppositely charged attract; and also, that excited electrics attract uncharged bodies which are conductors, a case that is evidently reducible by the principles of induction to that of charged bodies. It should be observed in passing, that these attractions and repulsions are quite distinct, in fact, from what we have called the attractions and repulsions of the electricities in our statement of the laws of induction. The experimental investigation of the laws of the electric forces was a work of great difficulty; and Coulomb had the high merit of commencing and completing it. The chief instrumental means that he employed in this work was the Balance of Torsion, a fine apparatus of his own invention, whose general form and principle we need not here describe, as a separate article has been devoted to it. When the Torsion Balance is formed especially for electric experiment, the lever or needle suspended by the torsion thread is a slight rod of nonconducting matter, bearing at one end a small and light-conducting sphere. The other electrified body, or the carrier, is in the simplest case a similar conducting sphere; and it is attached to a long insulating stem by which we introduce it through an opening in the glass case into the zero-position of the first sphere. To determine, by means of this apparatus, the relation between the electric force and the mutual distance of the bodies, the carrying ball is charged and introduced into its proper position, when it shares its charge with the other ball and repels it to a certain distance. At this distance the force of torsion is evidently equal to the electric repulsion. By causing the force of torsion to take various definite values, as we can do at pleasure, we are able to keep the moveable ball in equilibrium at various measurable distances from the fixed ball; and this while the two charges are sensibly constant. And then by comparing the different forces of torsion with the corresponding distances of the balls, we find that the mutual repulsion of the balls is inversely proportional to the square

of their distance. The attractive force of the two balls when oppositely charged is found to obey the same law. This case is managed by first charging the moveable ball and removing it by the torsion force to some distance from its zero-position, and then charging the carrier with the opposite electricity and putting it into position in the apparatus, and observing the simultaneous values of the torsion force and the distance as in the former case. For determining, further, the relation between the electric force and the quantities of electricity upon the balls, we must be able first of all to obtain isolated charges which are quantitatively related to one another in a perfectly definite way; for otherwise we can institute no comparison between different forces and the corresponding charges. To obtain charges thus related to one another, Coulomb adopted a very simple method. He took two perfectly similar conducting balls, of which one was charged and the other not: he placed these in contact with one another; and he took it as an axiom that after separation the balls were equally charged, and each therefore charged with half the quantity of electricity originally possessed by the one. In this way several submultiples of a given charge could be obtained and experimentally compared in the Torsion Balance. Suppose that the two balls in the balance were charged and in position, and that the torsion force and the distance of the balls were noted; that then the carrying ball were withdrawn and put in contact with a perfectly similar and equal uncharged ball, and finally restored to its position in the apparatus. The force of torsion that would be now required to preserve the original distance of the balls would be less than formerly, the repulsion of the balls having diminished. The charge upon the carrier might be again halved by a similar process: the charge upon the moveable ball might be also subdivided at pleasure; and the subdivisions of both charges might be conducted in any order, separately or together. In this way, and by a great number and variety of experiments, Coulomb proved, that the attractive and repulsive forces of the balls vary as the product of their charges. The laws above stated may be simply expressed in one mathematical formula. Let P and Q be the charges upon two small spheres, D the distance between the centres of the spheres, and F the attractive or repulsive force: then $F = \frac{P Q}{D^2}$. We can even include in

this formula the directions of the forces as attractive or repulsive, if we agree to affect all vitreous charges with the sign $+$, and all resinous charges with the sign $-$; for on this understanding, all positive values of F derived from the formula will indicate repulsions, and all negative values attractions. Such are the simple laws which regulate the attractions and repulsions of small charged balls, or of *charged points*, if we may so speak. Resting as these laws do upon rigorous

experimental grounds, they have been universally adopted as first principles by the cultivators of the mathematical theory. They have been questioned, however, in recent times, especially by Sir W. Snow Harris, who has attempted an experimental revision of this and other elementary points in the theory of electricity. The results which he obtained were certainly such as to throw some doubt at first upon the recognized laws of the electric forces; but it is now understood by those familiar with the subject, that the results of Coulomb's labours have been absolutely untouched, if not rather confirmed. The reader who desires full information upon these points may consult a paper by Professor W. Thomson, in the *Philosophical Magazine* for July, 1854. It will be evident that, within certain limits, the method of experimental inquiry described above might be still followed, though the electrified bodies were of various forms and magnitudes. But there is another method, which we owe still to Coulomb, and which may be followed in cases that would be unmanageable by the method of torsion. If one of the electrified bodies, for example, were very much greater than the other, the smaller body might be attached to the end of a light nonconducting lever and made to oscillate round a fixed point in front of the large body. The electric attraction in this case would supply the place of gravitation in the common pendulum; and the values of the attraction for different distances of the bodies would be proportional, according to the law of the pendulum, to the squares of the number of oscillations performed in a given time at those distances. By varying the distance, and observing the number of oscillations performed in a given time, we could therefore approximate to the law of the force in any given case. It should be observed, that this method of oscillations was also employed by Coulomb for the direct confirmation of those fundamental results already described as obtained by the method of torsion. As the first result then of these experimental researches of Coulomb, we have obtained a general mathematical formula of great simplicity, which expresses the entire law of the electric forces in the fundamental case of two charged points. And in more complex cases many accurate numerical results have been obtained, which are of use not for suggesting a general mathematical expression of the law of force in the case of given conductors, but for testing and confirming the results of a simple mathematical theory founded upon the equation $F = \frac{P Q}{D^2}$, and upon the laws of induction and distribution. For some developments upon these points see a subsequent article concerning IMAGES, ELECTRICAL. We should not leave this subject without referring to the dissipation of electricity from the charged bodies in the course of experiment. In the researches of

Coulomb and of those who have followed in his steps, this was found to be a most important element. It is in fact very evident, that in virtue of the dissipation the charges experimented on will be continually changing in quantity, and this independently of the will of the operator. Without entering into details, it may be stated that Coulomb certainly and completely overcame this difficulty in his researches, partly by preventing the dissipation as far as possible, and thereafter by taking fully into account the effects of the dissipation that remained.

4. We may now consider briefly the *Distribution* of electricity upon conductors. It is a fundamental proposition in this branch of the subject, that a charge bestowed upon an insulated conductor is distributed wholly over its external surface, and not in any degree throughout its mass or over interior surfaces. We exclude, of course, the case of an interior surface which envelops a charged and insulated body, a case well exemplified in Faraday's arrangement of the ice pail A and the enclosed carrier C. In proof of the proposition that we have now stated some striking experiments might be adduced. The apparatus employed in one of these is represented in the adjacent cut. It consists of an insulated

Fig. 5

conducting sphere, and two hemispherical conducting shells which are attached to insulating handles. The shells fit accurately to the surface of the sphere, so as to envelop the sphere, in contact with it and with one another. When we charge the sphere and then cover it with the hemispherical shells, we find that the surface of the latter, that is, the external surface of the whole conducting mass, is now electrified. And still more, when the shells are withdrawn by their insulating handles, we find that they are separately electrified, and that the sphere is perfectly discharged, presenting no trace of its original electricity. This is a clear proof that the charge was distributed wholly over the external surface. In further illustration take a hollow metallic cylinder, such as the ice pail A in the diagram upon induction. Let such a conductor be charged, and let the electric state of its various parts be tested by the proof plane. It will be found that the proof plane receives a sensible charge from any point of the external surface, but none whatever from a point of the interior surface; a clear proof that the electricity is distributed in accordance with the proposition. Like results may be obtained with perforated shells of conducting matter, whatever be the forms of the shells, provided they have closed or nearly closed surfaces. The figure represents one of the curious arrangements which Faraday has made in illustration of this subject. A conical bag of muslin has its mouth bounded by a metallic ring which is sup-

ported by an insulating stem. A silk thread attached to the apex of the cone passes through the ring. When we charge the ring and the bag and employ the proof plane, we find no trace of electricity upon the interior surface of the muslin, while we receive considerable charges from its outer surface. By drawing the thread we turn the cone inside out, and we find that the entire charge has changed surfaces, the inner surface being still destitute of electricity. As a

Fig. 6

last illustration: if we dig a small and sharp cavity in a spherical or other conductor and then charge the conductor, we find that the proof plane takes no charge whatever from the bottom or the sides of the cavity. From these and other instances we conclude, that when a charge is bestowed upon any connected body of conducting matter, it is distributed wholly over the external surface, and not in any degree through the interior of the mass, or even upon *surfaces* that are properly internal or enveloped. In all further questions therefore about the distribution of charges, we can have respect only to the electric intensities at the various points of conducting surfaces. The general question of distribution has been so far stated and answered in our remarks upon induction. The general statement there made may be now repeated and explained, and so far proved: that in all inductive and distributive actions the two electricities conduct themselves as if they were self-repulsive and mutually attractive with forces varying inversely as the square of the distance and directly as the product of the quantities of electricity. It must be noticed that in this statement we extend the assertion of a self-repulsive force both to the mutual actions of similar charges and to the action of every single charge upon itself. When conductors of certain forms are insulated and electrified, the simplest examination is sufficient to show that the charges are not uniformly distributed. If the conductor, for example, be a long cylinder with hemispherical ends, the attraction of light bodies will be evidently twice as powerful at the ends as at the middle of the cylinder; a result that indicates a greater accumulation of electricity at the ends than at the middle. But a much more accurate method of investigation than this is required for the true determination of the distribution in any case; and Coulomb supplied such a method by means of the Torsion Balance and the Proof Plane. When the Proof Plane is put in contact with any part of an electrified conducting surface, it becomes electrically an element of the surface; and when it is removed it retains a charge equal to the quantity of electricity resident upon the element that was covered by the proof plane. By successively discharging the proof plane, and applying it to different points of the given sur-

face, we obtain a series of small charges which have this definite relation to one another, that they are the quantities of electricity resident upon *equal* superficial elements in the given distribution. Now the natural measure of the electric intensity at any point of a charged surface is just the quantity of electricity resident upon a given and very small superficial element situated at the point in question; so that by means of the proof plane we can exhibit the various electric intensities of any particular distribution in the form of isolated charges that can be quantitatively compared with one another apart from all disturbing actions by means of the Torsion Balance. This is the simple theory of the employment of the Proof Plane in the experimental study of the laws of distribution. The theory of the employment of the Torsion Balance in this investigation is equally simple. The proof plane, when charged by contact with the surface, is introduced to the position of the fixed ball of the balance, where it attracts the moveable ball and gives it, as we otherwise know, a constant proportion of its own charge, and then repels it to a certain distance. By giving a proper value to the force of torsion we can keep the balls at any assigned distance from each other. When the torsion force which corresponds to the assigned distance is noted, the proof plane is withdrawn and applied to another point of the surface, and the moveable ball is perfectly discharged. The experiment is repeated in the same form for the new point of application of the proof plane, and the force of torsion for the same distance as before is determined. The process may be repeated for any other points of the charged surface. Now since the distances between the two small charged bodies in the balance are the same in the several experiments, the torsion forces which have been determined are simply proportional to the products of the charges upon the two bodies. But these products are proportional to the squares of the original charges upon the proof plane, since the latter body gives a constant proportion of its charge to the ball. And the charges drawn from the surface by the proof plane are therefore proportional to the square roots of the observed forces of torsion. By the simple calculations thus indicated, we can determine accurately the original charges of the proof plane and the electric intensities which are measured by them. It should be noticed, however, that the results thus obtained require correction, because of the gradual dissipation of the given charge. It is evident that two successive contacts of the proof plane cannot give the *simultaneous* intensities at the points examined, for the charge of the conductor diminishes in some degree during the interval between the contacts. The serious difficulty thus arising was met successfully by Coulomb in his researches upon this subject. He determined the laws of the dissipation, and corrected

his results accordingly. The mode of correction that he generally adopted in his experiments is worthy of special notice for its rigour and simplicity. The electric intensity at one point of the surface was determined by a single observation with the proof plane and the balance. After the shortest possible interval of time, the intensity at a second point of the surface was similarly determined; and after an equal interval the intensity at the first point was again observed. The second result and the arithmetical mean of the first and last results were then taken as the accurately simultaneous intensities at the points examined. When greater accuracy was desired, the mean of a greater number of results was taken; for in this way the unavoidable errors of separate experiments had their influence upon the final result eliminated or greatly diminished. By the method of investigation that we have now described, every actual case of distribution may be subjected to rigorous examination. A few of the simpler facts observed in regard to distribution may be now stated. Upon an insulated conducting sphere the distribution of a charge is uniform, subject always, however, to unlimited variations in virtue of inductive actions from without. Upon a prolate spheroid the intensity of the electricity at the poles exceeds that at the equator. The converse holds in the case of an oblate spheroid. In general, the distribution of a charge upon a conducting surface approaches to or departs from uniformity according as the form of the charged surface approaches to or departs from perfect roundness, and the electricity is always distributed with greatest intensity at the extremities of the greatest dimension. One case of distribution may be here quoted from Delarive's work on Electricity. An insulated cylinder, 2 inches in diameter and 83 in length, terminated by hemispherical surfaces, was charged and examined by Coulomb's method. The values of the intensity at the middle of the cylinder, at ten inches from the extremity, and at the extremity, were found to be as 100, 125, and 230. The electric intensity at any point of a charged surface depends, as we have seen, upon the general form of the surface and upon the position of the point in the surface. It depends also, and essentially, upon the value of the curvature in the immediate neighbourhood of the point in question. The greater the curvature at any point the greater is the intensity if other things are equal. And so powerful is this influence of curvature, that if a conducting surface be formed with very sharp and prominent edges, angles, or points, it will be impossible to retain any charge upon the body; for the intensities at the salient parts of the surface rise to the limiting value of discharge through the air, and this while there is hardly a sensible charge upon the body as a whole. The two influences that we have mentioned, that of the distant parts of the surface, and that of the curvature at the

point in question, may be so combined that the one shall annul the other. An angle, or point, for example, however sharp and prominent, will have no discharging influence if it be so enveloped by other distant parts of the body as to be considerably internal in relation to the entire conducting surface. These and other facts lead us to the conclusion, that every insulated charge possesses a property which is equivalent to a force of self-repulsion or expansion. For a view of the evidence by which our former statement of the quantitative law of this force is supported, we may refer the reader to the article entitled *FOURTH, ELECTRIC*. Some important results are obtained when two insulated conductors are placed in contact with each other, so as to present one conducting surface. When a surface of this kind is charged, it is observed that the law of distribution depends only on the *forms* and *magnitudes* of the two bodies, provided they are both good conductors. Whether the two bodies consist of the same or of different kinds of conducting matter, and whether both bodies be solid or the one be solid and the other hollow even to the utmost thinness actually attainable, the distribution is sensibly the same for the same forms and magnitudes of the two bodies. And hence we draw the important inference, that there is no electrical relation among the different kinds of matter analogous to that of specific capacity for heat. One of the most interesting cases of distribution is that upon two spheres which are in contact with each other. This case was experimentally studied by Coulomb with great accuracy. It was afterwards taken up by Poisson in his developments of the mathematical theory; and the several quantitative results that he obtained coincided so closely with those of Coulomb as to confirm very powerfully both the first principles of the theory and the difficult mathematical processes founded upon them.

1. Before proceeding to the subject of *discharge*, we may attend briefly to the laws of *disigned electricity*, and to the principles of the methods usually adopted for the accumulation of charge. We have seen that when two insulated and electrified conductors are put in contact with each other, they share the given charge between them in a proportion depending upon the forms and magnitudes of the surfaces. In these circumstances, the portion of the total charge that is received by one of the conducting surfaces increases as the magnitude of that surface increases relatively to that of the other surface, though not exactly in the same ratio. In much the same way, if an electric machine, or electrophorus, or other active source of electricity, be put in connection with an insulated conductor, it will give a charge to it very nearly proportional to the magnitude of the conducting surface. Hence the simplest way of obtaining increasing charges from a given source, say from a given machine kept at a given rate of work, is to in-

crease, or to virtually increase, the surface of the Prime Conductor. This was done by Volta, in his invention of the Secondary Conductors, which are nothing more than a system of well insulated conducting cylinders, which have their extremities rounded to prevent the rapid dissipation of the charge. When these cylinders are placed in connection with the prime conductor and with one another, they present a large conducting surface to the source, and receive a charge proportionally great. This method of accumulation is subject to grave inconveniences in practice, as it often requires an unmanageable extent of conducting surface, and is always attended with a rapid loss of the charge by dissipation in the air. The other method, now to be described, is free to a great extent from such inconveniences, besides possessing the advantage of an actual accumulation independent of an increase of surface. We know that a charge of any desired intensity may be developed and sustained in an *uninsulated* conductor. All that is necessary to this effect is, that another conductor be insulated and charged and brought into the neighbourhood of the former, but not into conducting connection with it. The opposite electricity of the uninsulated conductor is at once attracted, and the other electricity is repelled into the ground. The distribution of the inducing charge is also affected, a greater portion of the charge being now determined to that part of the surface that is adjacent to the uninsulated body. Suppose now that the charged conductor is in permanent connection with the prime conductor of the machine, and electrified to the utmost intensity attainable. When the uninsulated body is brought up towards its surface, the distribution upon the prime conductor and the connected body will be immediately changed according to the above law; and if the machine be still wrought the diminished intensities of the distribution will be restored to their former values, as we know by direct observation. Here then we have an instance of accumulation of electricity upon the prime conductor and connected bodies by simple inductive action. The amount of accumulation depends upon the distance between the two conductors, augmenting rapidly as this distance diminishes, and subject indeed to no limit of its increase except such as arises from the nature of the interposed nonconductor or dielectric, which admits of discharge through its mass when the intensities of the charges have reached certain values. To make the limiting intensity as great as possible, we employ glass or other solid nonconductors as the medium between the two conductors. The adjacent cut represents the glass plate condenser, one of the simplest arrangements that can be adduced in illustration of this subject. Two squares of metallic foil are pasted on the opposite sides of a square of glass, so as to leave a considerable edge, *v*, of the glass uncovered all round. To the upper parts of the two sheets of

foil two pith ball pendulums are attached, as represented in the figure. We charge the apparatus by uninsulating one of the metallic sheets, B, and connecting the other, A, with the prime conductor of the machine.

Fig. 7.

As the machine is wrought, the pendulum *a* rises, while *b* remains at rest in contact with B; and the condenser is fully charged when *a* has reached a stationary position. If now B be first insulated, and the connection between A and the prime conductor be then broken, the apparatus will remain charged, and the positions of the two pendulums will be unchanged. We infer from the divergence of *a* that the metallic sheet with which it is connected is electrified, but this electricity is not to be confounded with the charges that have been accumulated in the apparatus. The divergence of *a* is due in fact to a free charge disposed upon the external surface of A, a charge that A receives independently of the inductive action of B. Besides this free charge there are two opposite and powerful charges disposed upon the internal surfaces of A and B. This is an inevitable inference from the simplest principles of induction; but it may be otherwise proved in the present case by direct observation. When the apparatus has been charged and insulated, so that *a* is repelled and *b* not; let the knuckle be presented to the sheet A—a spark passes; the pendulum *a* falls at once to permanent contact with A, and *b* at the same time ascends. By drawing a charge from A, we have thus liberated a part of the charge of B from its internal surface, where the entire charge was originally confined by the inductive action of the more powerful charge upon A. The pendulum *a* remains in contact with the metallic sheet, because the entire charge of A is confined to the internal surface by the action of the now more powerful charge of B. Charges which are thus confined, so as to produce no inductive effects at external and accessible points are said to be *disguised* or *dissimulated*. By presenting the knuckle now to B, we partially discharge it; the pendulum *b* falls and *a* rises as before. By again discharging A, the pendulum *b* rises a second time; so that we have thus liberated a second part of the entire charge originally accumulated on the inner surface of B. In this way we may draw dozens of successive charges from the two plates before the condenser is discharged; a clear proof of the accumulating power of the arrangement, if we observe how much electricity is withdrawn, for example, by the first partial discharge of A. The arrangement possesses the further advantage of retaining the accumulated charges for a great length of time. The facts now stated find practical application in two of the most useful elec-

trical instruments, the Condenser and the Leyden Jar. Both instruments are founded upon the principles of disguised electricity; but they are of different forms, which are suited separately to the two ends usually aimed at in the accumulation of charges. The use of the Condenser is, to condense weak charges, or to increase the intensity of electricity derived from a given source by drawing upon the quantity, so as to make the charge measurable, or at least sensible. For a view of the form and theory of this instrument see the article on CONDENSER. The use of the Leyden Jar, on the other hand, is to accumulate great quantities of electricity for the purpose of powerful discharge. For a description of the instrument, we may refer to the article on BATTERY, ELECTRIC; but it may be here stated that the Leyden Jar is virtually the same as the glass plate condenser already described; only the glass dielectric is, in the one case, a square plate, and in the other, the wall of a wide mouthed phial. The mouth of the phial is closed by a nonconducting plug, and this is pierced by a conducting rod, which is terminated without by a knob and within by a chain or wire that touches the internal metallic coating of the Jar. The instrument is charged by connecting the knob with the Prime Conductor, and the outer coating with the ground, or *vice versa*. The greatest part of the electricities thus accumulated may be discharged instantaneously through any sufficiently conducting path established between the knob and the outer coating. And we can increase in any degree the power of discharge obtainable in this way from a given machine, by connecting a number of Jars together, giving them virtually one outer coating and one inner coating, an arrangement which is called an Electric or Leyden Battery.

6. We may now consider very briefly some of the simpler phenomena of *Discharge*. These phenomena are presented on a grand and terrific scale in the effects of lightning, such as the fusion of metals, the splintering and rending of trees, the shattering of the hardest rocks, and the destruction of animal and vegetable life; effects that can be exhibited on a very formidable, though a much smaller scale, by the Leyden Battery. Generally, when a discharge passes through matter of an inferior conducting power, it produces a very sensible mechanical disturbance among its particles. For the exhibition of these effects we make use of the Leyden Jar or Battery and the Universal Discharger or other similar instrument. The universal discharger is a simple arrangement of insulated metallic rods or wires, by which we are enabled to establish an interrupted conducting path between the coatings of the battery. In the interruption of the circuit we place the body that we wish to examine; and it is supported in that position by a nonconducting table placed under it. When the interruption of the circuit is short enough, and the charge

of the battery strong enough, the discharge traverses the body, and produces the desired effect as soon as the end of the circuit is brought up to the knob of the battery. In this way pieces of wood and stone and other nonconductors are violently fractured and projected out of the circuit. To this class of actions we must refer the occasional fracture of the walls of Leyden Jars by discharge between the coatings through the glass when the jars are too strongly charged. The disruptive action of discharge can be confined in certain cases to one part of the nonconducting mass that is placed in the circuit. The famous experiment of the pierced card is an instance. The interruption of the circuit in this experiment is terminated by two metallic points; and the body traversed by the discharge is a card of stiff paper or pasteboard, which is placed obliquely in the interruption of the circuit, so that its opposite surfaces are very near the discharging points. When the discharge passes, the card is pierced, but not rent or otherwise injured. The small perforation is generally close to the negative point, and presents a burr upon each surface of the paper as if it had been formed by two threads drawn violently through the card in opposite directions. By discharge a small hole may be pierced even through a sheet of glass without the glass being cracked or otherwise injured. All that is necessary for this effect is, that the points of the discharger be placed opposite to each other, and in contact with the surfaces of the glass, and that one of the points be enveloped with a drop of oil. Such facts clearly prove that when discharge traverses a nonconducting mass it produces great mechanical commotions among its particles. In the case of liquids and gases we cannot expect such permanent results as we have found in the case of solids; but here also we have clear proofs of powerful mechanical action. Thus, if the two ends of the interruption of the circuit be made to dip near each other under the surface of water, the discharge projects the water out of its path with great force; and in another arrangement, where the water is contained in a well closed phial, the commotion produced by a powerful discharge bursts the phial, and disperses the glass and water in all directions. In air and the gases the commotions produced are as evident as in solids and liquids, producing sounds and expansions of various intensities according to the strength of the discharge. The suddenness and intensity of the expansion are well illustrated in the *electric mortar*, a small and strong phial of glass which is perforated by two wires, and has its mouth closed by a ball of cork. When a discharge passes along the wires and through the air or gas enclosed in the phial, the sudden expansion projects the cork with considerable force. Kinnersley's thermometer, represented in the adjacent cut, consists of a large upright tube of glass, closed at both ends, and opening at the bottom into a small

tube which is bent upwards and open at the top. The ends of the large tube are traversed by conducting rods which are terminated within by knobs. The tubes contain water, as represented in the figure, to a level considerably above the mouth of the small tube: so that the air surrounding the knobs is confined to an air-tight chamber. Accordingly, when a discharge traverses the rods and the interjacent air, the water is launched upwards in the smaller tube with a sudden and powerful force, and immediately falls again, but not accurately to its original level. The apparatus gives in this way a very elegant proof of the sudden and transient expansion produced by discharge through air; but it proves also the existence of a more permanent though smaller expansion, by the permanent rise of the level in the smaller tube. The latter expansion is due to heat which is developed in the air by discharge, and which is lost not suddenly but by degrees. The calorific, illuminating, and inflaming actions of discharge are exhibited in a great variety of beautiful experiments that we have not space here to notice. The appearance of the electric spark and its inflaming power are known to all. Of the heating power of discharge we have had an instance in the experiment with Kinnersley's Thermometer. More marked effects of this kind are produced by the passage of considerable charges through attenuated masses of metal, such as thin leaves and fine wires. It requires no considerable charge to raise a fine iron wire to a red heat. With stronger discharges the metal is instantaneously fused into drops, or even dispersed in vapour. In this way a wire of metal which is immersed in a vessel of cold water can be melted into drops in an instant. The last effect of discharge that we shall notice is the *Physiological*, or the electric shock, which rises in intensity with the strength of the discharge, from a slight nervous commotion to the instant destruction of life. When we touch the outer coating of a charged phial with one hand, and bring the other up to the knob, the discharge of the electricities is effected through the body; and a peculiar sensation is felt, which, to be understood must be experienced. It might perhaps be described as a sudden and violent swelling of the muscles of the arms, in its gentler forms. With weak charges the shock is felt in the hands only; with stronger charges it is felt in the arms. When it is felt painfully in the chest, a stronger charge would be dangerous. The circuit may be formed as well by a number of persons with hands joined as by one; and in this case the two free hands at the ends of the circuit are brought up respectively to the outer coating and the knob. The shock is felt at the same instant by all the members of the circuit. There is a famous experiment of the French philosophers upon record, in which a whole regi-

Fig. 8.

ment of granules was overthrown at one blow by discharge from a Leyden Jar. The shock rises in intensity, as we have said, with the strength of discharge. It requires no very powerful charges to kill mice, birds, rabbits, and other small animals; and in many experiments, discharges are employed that would be sufficient for the destruction of any animal. The state of the animal frame after death by electric discharge or by lightning has been made the subject of diligent investigation, but no determination has been arrived at in regard to the organ or set of organs especially injured. But there can be little doubt that death by electric discharge is due chiefly if not wholly to an excessive shock in the nervous system. For additional information upon the laws of discharge see the article on that subject.—Upon the theories of electricity we cannot here dwell at any length. We shall merely state their fundamental assumptions. According to *Franklin's Theory*, the phenomena of electricity are due to the special properties and actions of a subtle kind of matter called the *Electric Fluid*. This fluid is self-repulsive, and attracts the common kinds of matter, and is reactively attracted. When a body is in a natural or electrically unexcited state, the attractive force of the matter is balanced by the self-repulsive force of the electric fluid, and the body is said to be saturated with electricity. When a body possesses more or less of the electric fluid than corresponds to the state of saturation, it is excited or charged, positively or by excess in the state of vitreous charge, and negatively in the state of resinous charge. These assumptions give apparently simple explanations of some of the elementary facts, especially of the electric force, the simpler facts of induction, and the laws of charge. According to the theory of *Dufay and Symmer*, there are two electric fluids, the *Vitreous* and the *Resinous*. Each fluid is self-repulsive, and each attracts the other. The theory of a single fluid and that of two fluids appears to be of much the same value, as the facts explained by the one are generally capable of being equally well explained by the other. The former theory, however, is liable to the special objection that it necessarily infers a mutual force of repulsion among the common kinds of matter. For a brief statement of *Faraday's theory* see *INDUCTION*.

Electricity: Applications of. Electricity is no longer an abstract or unapplied science: it has become an available source of power to the *Mechanician*, the *Chemist*, the *Engineer* civil and military, the *Physicist*, the *Chemist*, the *Observer*, the *Drama* *Critic*, &c., and, in short, to all persons interested in the practical work of advancing civilization through the instrumentality of science. It is but a very slight comment that we can give in this dictionary of its various

CONSERVATION, REGENERATION, TELEGRAPH, and THUNDER-BOLT. We expressly warn our reader that only a brief notice of the efficiency of this very valuable agent can be presented under any of the heads now mentioned.

Electricity: Correlation of, Mechanical Equivalent of. Is the second Dissertation prefixed to this volume, as well as in *ARTICLE FORCE, CORRELATION AND CONSERVATION* or, the grand principle now lying at the foundation of all physics, has been illustrated and enforced. The special question at present is, whether this correlation holds in the case of Electricity; whether other forces, as they seem to disappear, may assume its form; whether, when it seems to disappear, it only takes on some other mode of energy; and, finally, whether, under every variety of circumstance, it has a definite, invariable, and ascertainable mechanical equivalent? As to the general fact of correlation, it has long been established as belonging to the electric force. Friction or mechanical effort evolves it; and, in its turn, it can realize important mechanical effects. Heat evolves it, and the force so produced evolves heat. Electricity calls into existence potent magnetic polarities; and the magnet produces powerful electric currents in a coil of wire. The current becomes chemical affinities, and sometimes compels bodies to combine; while those changes in affinities, that constitute the sources of energy in the pile or the galvanic battery, give rise to electric energies which are well nigh irresistible—energies that dissolve the closest and firmest atomic unions, and which in the telegraph are going far to annihilate both space and time. The main question, however, remains,—amid all such transformations do we recognize the disappearance and production of forces that are exactly equivalent. Unless equivalence is established, there is no proof of identity. It is only just to state that science owes the starting, and by far the greater part of the elucidation of this inquiry, to the sagacity, the accuracy, and unswerving patience of Mr. Joule, sometimes working apart, and at other times in connection with his friend and fellow-discoverer, Professor William Thomson. We can give here but the briefest outline of the results arrived at by Mr. Joule and a few other physicists.—In a recent interesting letter to the editor of the *Philosophical Magazine*, Mr. Grove announces a curious experiment, inaugurating a novel mode of investigating this substance. It seems this. Take a Leyden charged, and therefore on the point of a by the spark: bring into its neighborhood Cuthbertson's electrometer—it will repel the ball of the electrometer, and so exercise a mechanical effect. That moment the tension diminishes, and the jar is no longer on the point of discharging a definite quantity of electricity as we have instead a tonical effect. In the

same manner, whenever an electric current causes the attraction of two pieces of an apparatus, if these two pieces, yielding to this attraction, are set in motion, a suitable and definite diminution of the intensity of the current is observed: the inverse also holds true.—But the phenomena may be better illustrated by special detail. It is well known that when the current passes through a thin wire, heat is generated. Now that heat may be measured by surrounding the wire with water. The increase of the temperature of the water is the measure of the heat. But by surrounding a piece of soft iron by this wire in a coil, magnetic force is produced; and it can be proved that the quantity of electricity which, when transformed into heat by the resistance of the medium, is enough to raise the temperature of a pound of water by 1 degree, produces an attractive magnetic force by which a weight of 772 pounds may be raised a foot high—the exact mechanical equivalent of that definite amount of heat. Again, when the conductor is cut in two, and its two ends dipped into a vessel of water, electricity manifests itself as an analytic force, and decomposes the water into its aerial elements, oxygen and hydrogen. These may be re-united, and on their re-union they produce heat. Now, accurate investigation has established, that an electric current of known strength, which, when transmitted by a conductor into heat, is enough to heat one pound of water 1° , liberates—when employed on the decomposition of water—an amount of hydrogen by which, when it is burnt, exactly one pound of water can be raised from 0° to 1° .—Illustrations of this sort could be brought without end, showing that electricity, like the other energies, merely transforms itself,—that with regard to it also, the maxim holds, “Force never dies.”—It is highly important to know, in reference to this class of inquiries, that alike through Joule’s experiments and theoretical deductions from chemical principles, the electromotive force of any battery can be laid down with accuracy in thermal units, so that, beginning at its origin, we can trace the action and history of the entire force until it evolves its final effect. See on this subject an instructive paper by Professor W. Thomson, in *Philosophical Magazine* for December, 1856.

Electricity, Atmospheric. 1. It may be pointed, to avoid circumlocution in this article, that every body in communication with the earth by means of matter possessing electric conductivity enough to prevent its electric potential from differing sensibly from that of the earth, will be called part of the earth. Moist stone,

*The conducting bodies are said to be of the same electric potential when, if put in conducting communication with the two electrodes of an electrometer, no electric effect is produced. When, on the other hand, the electrometer shows an effect, the amount of this effect measures the difference of potentials between the two bodies thus tested. A difference of potentials is also called electromotive force.

and rock of all kinds, and all vegetable and animal bodies, in their natural conditions, except in circumstances of extraordinary dryness, possess, either superficially or throughout their substance, the requisite conductivity to fulfil that condition. On the other hand, various natural minerals and artificial compounds, such as glass,—various vegetable gums, such as India-rubber, gutta percha, rosin,—and various animal products, such as silk and gossamer fibre,—when either in a very dry natural or in an artificially dried atmosphere, resist electrical conduction so strongly that they may support a body, or otherwise form a material communication between it and the earth, and yet allow it to remain charged with electricity to a potential sensibly differing from the earth’s, for fractions of a second, for minutes, for hours, for days, or even for years, without any fresh excitation or continued source of electricity. Again, air, whether dry or saturated with vapour of water, and probably all gases and vapours, unless ruptured by too strong an electromotive force, are very thoroughly destitute of conductivity—that is to say, are very perfectly endowed with the property of resisting the tendency of electricity to pass and establish equality of potential between two bodies not otherwise materially connected.—2. Hence, when “the surface of the earth” is spoken of, the surface separating the solids and liquids of the earth from the air will be meant; and when the more qualified expression “outer surface of the earth” is used, inner surfaces of vesicles, or the surfaces bounding completely enclosed spaces of air, must be understood to be excluded. Thus, the surface of a mountain peak; the surface of a cave, up to the inmost recesses of the most intricate passages; the surface of a tunnel; the surface of the sea, or of a lake or river; all the surface of a sheet of unbroken water in such a fall as that of Niagara; the surface of blades of grass and flowers, and of soil below; in a wood, the surface of soil, and of trunks and leaves of trees; the surface of any animal resting on the earth; the outside of the roof of a house; the whole inside surface of a room with an open window; all belong to the outer surface of the earth.—3. On the other hand, the moon, meteoric stones, birds or insects flying, leaves or fruit falling, seed wafted through the air, spray breaking away from a cascade or from waves of the sea, the liquid particles of a cloud or a fog, present surfaces not belonging to the earth, and between which and the earth’s surface differences of potential, and lines of electric force, may and generally do exist. 4. The whole surface of the earth, as defined above (§ 2), is at every moment electrified in every part, with the exception of neutral lines dividing portions which are negatively (resinously) from portions which are positively (vitreously) electrified. The negatively electrified portions are of very much greater extent, at all times, than those positively electrified;

and there may be times when the whole surface is negatively electrified, because in all localities in which electrical observations have been hitherto made, with possibly one remarkable exception,* the earth's surface is always found negative, day and night, during fair weather, and only occasionally positive in broken weather, or during an actual fall of rain in the immediate neighbourhood, if not exactly on the place of observation. If, then, at any one time there chances to be fair weather over the whole earth, it may be presumed that the whole outer surface of the earth is then negatively electrified, unless, judging from the possible exception above alluded to, we are still to expect positive electrification in some extreme positions.—5. As yet nothing is known regarding the electrification of air itself, or of clouds or other matter suspended in the air, except what can be inferred (see below, § 6) from the electrification of the earth's surface, and its variations, with which alone, as Peltier has remarked, the observations of "atmospheric electricity" hitherto published have dealt (see below, §§ 17–19). It is impossible, in the nature of things, to investigate the bodily electrification of a non-conductor by any observation whatever of electric action without it,† or in any way whatever, except by something equivalent to a determination of the magnitude and direction of the resultant force at every point of its mass.‡

* At Gnjara station, on the Peak of Teneriffe. "During the whole period of observation, by day and night, the electricity was moderate in quantity, and always resinous. This was during the period of N. E. trade wind, and within its influence, though above its clouds." [Professor Plazzi Smyth's Account of the Teneriffe Astronomical Experiment, *Philosophical Transactions*, 1858, and separate publication ordered by the Lords of the Admiralty.] The "electricity" here referred to was that acquired by an insulated conductor carrying a burning match in the air at some distance from the earth. If it were really negative, the earth's electrification at the place must have been positive; but the test as to quality may have been deceptive, owing to the highly insulating condition of both outer and inner surfaces of the glass shade inclosing the gold leaves, and to the circumstance of the testing piece of rubbed sealing wax having been applied possibly too near the gold leaves, instead of beside a remote part of the insulated rod. Professor Smyth assures the writer, that he considers the electrical experiment as not sufficiently complete or confirmed to allow any conclusion to be built on it, and regards it rather as an indication of the importance of making electrical observations with better apparatus, and more available time for using it, than the first Teneriffe scientific expedition afforded.

† According to Green's remarkable theorems, triply rediscovered by Gauss, Charles, and the writer of this article, all different distributions of electricity within a solid, which produce the same potential at its surface, produce the same force at every point without it, and the problem of finding a distribution of electricity, within the interior to produce a given distribution of potential at the surface, is indeterminate.

‡ Let X, Y, Z , be the components of the resultant force on a unit of electricity, if placed at any point x, y, z , in a mass of air or other non-conductor; and let ϵ denote the electrical density of the substance, that is to say, the quantity of electricity per unit of bulk actually possessed by the air in the neighbourhood of this point. Then, by a well known proposition

Towards this thorough investigation of the distribution of electricity within a non-conducting mass, it may be remarked, that a determination of the normal component of the force all round a closed surface is just sufficient to show the aggregate quantity of electricity possessed by all the matter situated within it.§ Hence observation in positions all round a mass of air is necessary for determining the quantity of electricity which it contains; and, therefore, the balloon must be put in requisition if knowledge of the distribution of electricity through the atmosphere is to be sought for.—6. Without leaving the earth, however, although we cannot thoroughly investigate the electrification of the air, we can make important inferences about it from observations of the electric density over the earth's surface, by a principle of judging which may be thus explained:—If the earth were simply an electrified body, placed in a perfectly insulating medium of indefinite extent, and not sensibly influenced by any other electrified matter, or by reflex influence from any conductor or dielectric in its vicinity, its electricity would be distributed over its surface according to a perfectly definite law, depending solely on the form of the surface, and deducible by a sufficiently powerful mathematical analysis from sufficiently perfect data of "geometry" (in the primitive sense of the term), or of what, in more modern language, is called geodesy. If the surface of the earth were truly spherical, this law would be simply uniformity. A truly elliptic oblateness of the earth would give, instead of uniformity, a distribution of electric density, in simple proportion to the perpendicular distance between a tangent (that is, horizontal) plane through any point and the earth's centre; according to which the electric density at the equator would be greatest, and would exceed that at either pole, where it would be least, by $\frac{1}{2} \frac{a}{b}$, a difference which, for the present, we may disregard.—7. The whole amount of electricity over the surface of any great region of mountainous country, or of forest land, or of soil and vegetation of any kind, or of streets and houses in a town, or of rough sea, would be very approximately the same as that on an area of unruffled ocean, equal to the "reduced" area of the irregular surface; but the distribution of the electricity over hill and valley, over the leaves and trunks of trees, and the surfaces of plants generally, and on the soil beneath them, over

of the mathematical theory of attraction, we have

$$\epsilon = \frac{1}{4\pi} \left(\frac{dX}{dx} + \frac{dY}{dy} + \frac{dZ}{dz} \right).$$

§ Let N be the normal component of the force at any point of a closed surface, ds an element of the surface, \int the sign of integration for the whole surface, and Q the whole quantity of electricity within it. Then, by a well known theorem of Green's, rediscovered as alluded to in a preceding note, we have

$$Q = \frac{1}{4\pi} \int N ds$$

the roofs, perpendicular walls, and overhanging or overhanging surfaces of buildings, and the surfaces of streets and enclosed courts between them, and over the hollows and crests of waves in a stormy sea, would be extremely irregular, with, in general, greater electric density on the more prominent and convex portions of surfaces, and less on the more covered and concave—quite insensible, indeed, in any such position as the interior of a cave, the soil below trees in a forest—even where considerable angular openings of sky are presented, or the roof or floor of a tunnel, or covered chamber, even although open to a considerable angle of sky.—8. If thus a perfect electro-geodesy gave a “reduced” electric density equal over the whole earth, we might infer that the electrification of the earth is not influenced by any electricity in the air. According to what has been stated above, there might in that case be either no electricity in the air, from the earth’s atmosphere to the remotest star, and (according to Faraday’s views) the lines of electric force rising from the earth might terminate in the surfaces of the moon, meteoric stones, sun, planets, and stars; or there might be, at any distance considerably exceeding the height of the highest mountain, a uniformly electrified stratum of equal quantity and opposite kind to the earth’s, balancing through all the exterior space the force due to the terrestrial electricity, and limiting the manifestations of electric force to the atmosphere within it; or there might be any of the infinite variety of distributions of electricity in space round the earth, by which the electric density at the earth’s surface would be uninfluenced.—9. But, in reality, the electric density varies greatly, even in serene weather, over the earth’s surface at any one time, as we may infer from (1.) the facts (established for Europe, and probably true in all the temperate zones of both hemispheres), that in any one place the electric density of the surface observed during serene weather is much greater in winter than in summer, and that it varies according to something of a regular periodicity with the hours of the day and night; and (2.) the consideration that there is often serene weather of day and night, and of summer and winter, at one and the same time, in different temperate portions of the earth. We may, therefore, consider it as quite established, that even in serene weather, the electrification of the earth’s surface is largely influenced by external electrified matter. Although we cannot (§ 5) discover the exact locality and distribution of this influencing electricity from its effects at the earth’s surface alone, yet it is possible, from the character of the distribution of the terrestrial electric density as influenced by it, to assign a superior limit to its height.* If at any one instant the electric density reduced to the sea level were distributed according to a

* If at any instant the co-efficients of the series of “Laplace’s functions,” expressing the terrestrial electric density reduced to the sea level, converged

simple “harmonic” law, or, more generally, according to a certain definite character of non-abruptness of variation easily specified in mathematical language,† the external influencing electricity might be at any distance, however great, for all we could discover by observations near the earth’s surface. But, little as we know yet regarding the diurnal law of electric variation in serene weather, it is, we may say with almost perfect certainty, not such as could give at any instant a distribution over the whole earth possessing any such gradual character as that referred to; and, therefore, we may, in all probability, from the character of the diurnal variation itself, say that its electric origin is not at a distance of many radii from the surface. On the other hand, when we consider that in temperate regions the velocity with which the earth’s surface is carried round in its diurnal course is from 500 to 900 miles per hour, we see clearly that any law of diurnal electric variation, established on observations even so frequent as once every hour, could not possibly fix the locality of the origin to within 100 miles of the surface; and as we have as yet nothing to go upon in the way of published observations more frequent than three or four times a day, towards establishing either the existence or the character of the diurnal law, we cannot consider it as proved by observation that the influencing electricity which produces it is even as near as the 50 or 100 miles limit which is commonly (but in the opinion of the writer of this article, most unreasonably) assigned as an end to the earth’s atmosphere.—10. The great suddenness of the electric variations during broken weather, and their close correspondence with beginnings, changes, and cessations of rain, hail, or snow, compel us (by a *common sense* estimate founded on an unconscious application of the mathematical law stated in the footnotes to the preceding § 9) to believe that their origin agrees in position with that of the showers, and to give it a “local habitation” and a name—Thundercloud.—11. The writer of this article has observed extremely rapid variations of terrestrial electrification during perfectly serene weather. Thus, in a calm summer night, with an unvarying cloudless sky overhead, and not the faintest ap-

ultimately with less rapidity than the geometrical series $1, \frac{1}{m}, \frac{1}{m^2}, \dots$ we might be sure that there is

electricity in the air at some distance from the centre of the earth, not exceeding m times the radius of the earth’s surface. For the principles on which this assertion is founded, see a short article, entitled “Note on Certain Points in the Theory of Heat,” *Cambridge Mathematical Journal*, November, 1848.

† For instance, if in simple proportion to the cosine of the angular distance from any point of the earth’s surface, or more generally, if expressible by any finite number of “Laplace’s functions,” or still more generally, if expressible by a series of “Laplace’s functions,” with co-efficients converging ultimately more rapidly than any geometrical series.

pearance of auroral light to be seen, he has, in a temporary electric observatory in the Island of Arran, found large variations (as much as from a certain degree to double and back) in the course of a minute of time. The influencing electricity by which these variations were produced, cannot possibly (unless on the extremely improbable hypothesis of their being due to highly electrified extra-terrestrial matter moving very rapidly with reference to the earth) have been very far removed from the earth's surface. It is not impossible, and we have as yet nothing to make it decidedly improbable, that they were due to fluctuations up and down of aerial strata, perhaps those of the great atmospheric currents, in high regions of the atmosphere. Judging, however, from still more recent observations referred to below (§ 14), we may think it more probable that these remarkable variations in the observed electric force were due chiefly to positively or negatively electrified masses moving along within a few miles of the locality of observation.—

12. Returning to the subject of the distribution of electricity over the earth's surface at any instant, we may remark, that if over an area of several miles in diameter, of perfectly level, bare country, or of sea, the electrical density is sensibly uniform, we could not, without going up in a balloon, and observing the electric force at points in the air above, form any judgment whatever as to the distance from the earth at which the influencing electricity is situated. If, on the other hand, we find a very sensible variation in the electric density between two points of a piece of level, open country, or at sea, not many miles apart, we may infer as quite certain that there is influencing electricity not many miles up in the air, and not uniformly distributed in level strata. Nothing can be easier than to make this trial—only to observe simultaneously with similar instruments, similarly placed, at two neighbouring stations, in a suitable locality—and most interesting and important results are to be derived from it, as soon as arrangements can be made for continuing the requisite observations day and night, during various vicissitudes of weather, especially during a time of perfect serenity.—

13. Corresponding statements apply to a mountainous country, with this modification, that a very varied, instead of a uniform distribution of electric density, is, in such a locality, as explained above in § 7, the natural consequence of freedom from the disturbing influence of near electrified masses of air or cloud. The problem of accurately determining, from purely geometric data (§ 6), this undisturbed distribution over even the smoothest hillside, would infinitely transcend human mathematical power, although an approximate solution may be readily given for any piece of country over the whole of which both the inclination and the ratio of the height above the general level to the radius of curvature of the surface are small. For a rugged mountainous

country, the most perfect geometric data, and the most strenuous mathematical efforts, could scarcely lead us towards an approximate estimate of the inequalities of electric density which different localities must present without any disturbance from near electrified atmosphere. Hence, in a mountainous country—unless we find electricity strong in some locality where from the configuration of the surface, we correctly judge it ought to be weak if undisturbed, or weak where it ought to be strong, or unless, at least, we find some very decided deviation from any such amount of difference between two stations as, without being able to make a precise calculation, we can estimate for the difference due to figure—we cannot judge as to the influence of aerial electrification from simultaneous absolute determinations at any one instant alone. But of one thing we may be sure, that although the absolute amounts of the electrification at any two stations not far apart may differ largely, they must remain in an absolutely constant proportion to one another, if there is no electrified air or cloud near.—14. Hence, if we find observations made simultaneously by two electrometers in neighbouring positions, in a mountainous country, to bear always the same mutual proportion, we may not be able to draw any inference as to electrified air; but if, on the contrary, we find their proportion varying, we may be perfectly certain that there are varying electrified masses of air or cloud not far off. A first application of this test is described in the following extract from the Proceedings of the Literary and Philosophical Society of Manchester for October 18, 1859:—

“The following extract of a letter received from Professor W. Thomson, F.R.S., Glasgow, Honorary Member of the Society, &c., was read by Dr. Joule:—

“I have a very simple “domestic” apparatus by which I can observe atmospheric electricity in an easy way. It consists merely of an insulated can of water set on a table or window sill inside, and discharging by a small pipe through a fine nozzle two or three feet from the wall. With only about ten inches head of water and a discharge so slow as to give no trouble in replenishing the can with water, the atmospheric effect is collected so quickly that any difference of potentials between the insulated conductor and the air at the place where the stream from the nozzle breaks into drops is done away with at the rate of five per cent. per half second, or even faster. Hence a very moderate degree of insulation is sensibly as good as perfect, so far as observing the atmospheric effect is concerned. It is easy, by my plan of drying the atmosphere round the insulating stems by means of pumice stone moistened with sulphuric acid, to insure a degree of insulation in all weathers, by which there need not be more than five per cent. per hour lost by it from the atmospheric apparatus at any time. A little attention

to keep the outer part of the conductor clear of spider lines is necessary. The apparatus I employed at Invercloy stood on a table beside a window on the second floor, which was kept open about an inch to let the discharging tube project out without coming in contact with the frame. Theazole was only about two feet and a-half

Fig. 1.

from the wall, and nearly on a level with the window sill. The divided ring electrometer stood on the table beside it, and acted in a very satisfactory way (as I had supplied it with a Leyden phial, consisting of a common thin white glass shade, which insulated remarkably well, instead of the German glass jar—the second of the kind which I had tried, and which would not hold its

charge for half a day).—I found from $18\frac{1}{2}^{\circ}$ to 14° of torsion required to bring the index to zero, when urged aside by the electromotive force of ten zinc-copper water cells. The Leyden phial held so well, that the sensibility of the electrometer, measured in that way, did not fall more than from $18\frac{1}{2}^{\circ}$ to $18\frac{1}{4}^{\circ}$ in three days. The atmospheric effect ranged from 80° to above 420° during the four days which I had to test it; that is to say, the electromotive force per foot of air, measured horizontally from the side of the house, was from 9 to above 126 zinc-copper water cells. The weather was almost perfectly settled, either calm, or with slight east wind, and in general an easterly haze in the air. The electrometer twice within half an hour went above 420° , there being at the time a fresh temporary breeze from the east. What I had previously observed regarding the effect of east wind was amply confirmed. Invariably the electrometer showed very high positive in fine weather, before and during east wind. It generally rose very much shortly before a slight puff of wind from that quarter, and continued high till the breeze would begin to abate. I never once observed the electrometer going up unusually high during fair weather without east wind following immediately. One evening in August I did not perceive the east wind at all, when warned by the electrometer to expect it; but I took the precaution of bringing my boat up to a safe part of the beach, and immediately found by waves coming in that the wind must be blowing a short distance out at sea, although it did not get so far as the shore.—I made a slight commencement of the *electrogeodesy* which I pointed out as desirable at the British Association, and in the course of two days, namely, October 10th and 11th, got some very decided results. Macfarlane, and one of my former laboratory and Agamemnon assistants, Russell, came down to Arran for that purpose. Mr. Russell and I went up Goatfell on the 10th instant, with the portable electrometer (see Fig. 3), and made observations, while Mr. Macfarlane remained at Invercloy, constantly observing and recording the indications of the house electrometer. On the 11th instant the same process was continued, to observe simultaneously at the house and at one or other of several stations on the way up Goatfell. I have not yet reduced all the observations; but I see enough to leave no doubt whatever but that cloudless masses of air at no great distance from the earth, certainly not more than a mile or two, influence the electrometer largely by electricity which they carry. This I conclude because I find no constancy in the relation between the simultaneous electrometric indications at the different stations. Between the house and the nearest station the relative variation was least. Between the house and a station about half way up Goatfell, at a distance estimated at two miles and a-half in a right line, the number expressing the ratio varied from

Fig. 2

about 118 to 860 in the course of about three hours. On two different mornings the ratio of the house to a station about sixty yards distant on the road beside the sea was 97 and 96 respectively. On the afternoon of the 11th instant, during a fresh temporary breeze of east wind, blowing up a little spray as far as the road station, most of which would fall short of the house, the ratio was 108 in favour of the house electrometer—both standing at the time very high—the house about 850°. I have little doubt but that this was owing to the negative electricity carried by the spray from the sea, which would diminish relatively the indications of the road electrometer."—15. The electrometers referred to in the preceding extract were on two different plans. The first, or "divided ring electrometer," consists of—(1), A ring of metal divided into sectors, of which some—one or more—are insulated and connected with the conductor to be electrically tested, and the remainder connected with the earth. (2), An index of metal supported by a glass fibre, or a wire, stretched in the line of the axis of the ring, and capable of having its fixed end turned through angles measured by a circle and pointer. (3), A Leyden phial, with its insulated coating electrically connected with the index. (4), A case to protect the index from currents of air, and to keep an artificially dried atmosphere round the insulating supports—glazed to allow the index to be seen from without, but with the inner surface of the glass screened (electrically) by wire cloth, perforated metal, or tinfoil, to do away with irregular reflections on the index. In the instrument represented in the drawing (No. 2) above, the ring is divided into only two parts, which are equal, and separated by a space of air about $\frac{1}{8}$ of an inch. Each of these half rings is supported on two glass pillars; and by means of screws acting on a foot which bears these pillars, it is adjusted and fixed in its proper position. The index is of thin sheet aluminium, and projects in only one direction from the glass fibre bearing it. A stiff vertical wire, rigidly connected with it, nearly in the prolongation of the fibre, bears a counterpoise considerably below the level of the index, and heavy enough to keep the index horizontal. A thin platinum wire hooked to the lower end of this vertical wire, dips in sulphuric acid in the bottom of the Leyden phial. The Leyden phial is charged either positively or negatively; and is found to retain its charge for months, losing, however, gradually, at some slow rate, less generally than one per cent. per day of its amount. The index is thus, when the instrument is in use, kept in a state of charge corresponding to the potential of the inside coating of the phial. When one of the half rings is connected with the earth, and a charge of electricity communicated to the other, the index moves from or towards the latter, according as the charge communicated

to it is of the same or the opposite kind to that of the index. This instrument, as an electroscope, possesses extreme sensibility—much greater than that of any other hitherto constructed; and by the aid of the torsion arrangement, it may be made to give accurate metrical results. There are some difficulties in the use of it, especially as regards the comparison of the indications obtained with different degrees of electrification of the index, and the reduction of the results to absolute measure, hitherto obviated only by a daily application of Delmann's method of reference to a zinc-copper water battery, which Delmann himself applies once for all, to one of his electrometers (unless his glass fibre breaks, when he must make a fresh determination of the sensibility of the instrument with its new fibre). The high sensibility of

Fig. 2.—Portable Atmospheric Electrometer.

the divided ring electrometer renders this test really very easy, as not more than from ten to

twenty cells are required; and a comparison with a few good cells of Daniell's may be made by its aid, to ascertain the absolute value and the constancy of the water cells. The difficulty thus met is altogether done away with in another kind of electrometer, also "heterostatic," of which only one has yet been constructed—the electrometer of the portable apparatus shown in the third drawing. In it the index is attached at right angles to the middle of a fine platinum wire, firmly stretched between the inside coatings of two Leyden phials, and consists simply of a very light bar of aluminium, extending equally on the two sides of the supporting wire. It is repelled by two short bars of metal, fixed on the two sides of the top of a metal tube, which is supported by the inside coating of the lower phial, and has the fine wire in its axis. A conductor of suitable shape, bearing an electrode, to connect with the body to be tested, insulated inside the case of the instrument, in the neighbourhood of the index, and when electrified in the same way, or the contrary way, to the inside coatings of the Leyden phials, causes, by its influence, the repulsion between the index and the fixed bars to be diminished or increased. The upper Leyden phial is moveable about a fixed axis, through angles measured by a pointer and circle, and thus the amount of torsion, in one-half of the bearing wire, required to bring the index to a constant position, in any case, is measured. The square root of the number of degrees of torsion measures the difference of potentials between the conductor tested and the inner coating of the Leyden phial. In using the instrument, the conductor tested is first put in connection with the earth, and the torsion required to bring the index to its fixed position is read off. This is called the zero, or earth reading. The tested conductor is then electrified, and the torsion reading taken. In the atmospheric application, this is called the air reading. The excess—positive or negative—of its square root, above that of the zero reading, measures the electromotive force between the earth and the point of air tested. This result, when positive shows vitreous, when negative resinous potential in the air; if the index is resinous. By the aid of Baily's table of square roots, the indications of the instrument may thus be reduced to definite measure of potential, almost as quickly as they can be written down. Once for all, the sensibility of the instrument can be determined by comparison with an absolute electrometer, or a galvanic battery. In the portable apparatus a burning match is used—instead of the water-dropping system, which the writer finds more convenient than any other for a fixed apparatus—to reduce the insulated conductor to the same potential as the air at its end.—16. As has been remarked above (§ 4), it is the electrification of the earth's surface which has either directly or virtually been the subject of

measurement in all observations on atmospheric electricity hitherto made. The methods which have been followed may be divided into two classes—(1), Those in which means are taken to reduce the potential of an insulated conductor to the same as that of the air, at some point, a few feet or yards distant from the earth. (2), Those in which a portion of the earth (see above, § 1) is insulated, removed from its position, and tested by an electrometer, in a different position, or under cover. The first method was very imperfectly carried out by Beccaria with his long "exploring wire," stretched between insulating supports, on elevated portions of buildings, tree tops, or other prominent positions of the earth (see above, § 1); also, very imperfectly by means of "Volta's lantern"—an enclosed flame, supported on the top of an insulated conductor. On the other hand, it is put in practice very perfectly, by means of a match, or flame burning in the open air, on the top of a well-insulated conductor—a plan adopted, after Volta's suggestion, by many observers; also, even more decidedly, by means of the water-dropping system—described in the preceding extract—which has recently occurred to the writer, and has been found by him both to be very satisfactory in its action, and extremely easy and convenient in practice. The principle of each of these methods of the first class may be explained best by first considering the methods of the second class, as follows:—17. If a large sheet of metal were laid on the earth in a perfectly level district, and if a circular area of the same metal were laid upon it, and, after the manner of Coulomb's proof plane, were lifted by an insulated handle, and removed to an electrometer within doors, a measure of the earth's electrification, at the time, would be obtained; or, if a ball, placed on the top of a conducting rod in the open air, were lifted from that position by an insulating support, and carried to an electrometer within doors, we should also have, on precisely the same principle, a measure of the earth's electrification at the time. If the height of the ball in this second plan were equal to one sixteenth of the circumference of the disc used in the first plan, the electrometric indications would be the same, provided the diameter of the ball is small, in comparison with the height to which it is raised in the air, and the electrostatic capacity of the electrometer is small enough not to take any considerable proportion of the electricity from the ball in its application. The idea of experimenting by means of a disc laid flat on the earth, is merely suggested for the sake of illustration, and would obviously be most inconvenient in practice. On the other hand, the method, by a carrier ball, instead of a proof plane, is precisely the method by which, on a small scale, Faraday investigated the distribution of electricity induced on the earth's surface (see above, § 1), by a piece of rubbed shellac; and the same method, applied on a suitable scale, for testing the natural

electrification of the earth in the open air, has given, in the hands of Delmann of Creuznach, the most accurate results hitherto published in the way of electro-meteorological observation.*—

18. If, now, we conceive an elevated conductor, first belonging to the earth (§ 1), to become insulated, and to be made to throw off, and to continue throwing off, portions from an exposed position of its own surface, this part of its surface will quickly be reduced to a state of no electrification, and the whole conductor will be brought to such a potential as will allow it to remain in electrical equilibrium in the air, with that portion of its surface neutral. In other words, the potential throughout the insulated conductor is brought to be the same as that of the particular equi-potential surface in the air, which passes through the point of it from which matter breaks away. A flame, or the heated gas passing from a burning match, does precisely this: the flame itself, or the highly-heated gas close to the match being a conductor which is constantly extending out, and gradually becoming a non-conductor. The drops into which the jet issuing from the insulated conductor, on the plan introduced by the writer, produce the same effects, with more pointed decision, and with more of dynamical energy to remove the rejected matter with the electricity which it carries from the neighbourhood of the fixed conductor.

Electricity: Velocity of.—The velocity of the transmission of electricity has been a subject of careful inquiry, and of extremely in-

teresting experiments, on the part of several distinguished *Physicists*; foremost among whom rank Professor Wheatstone and MM. Fizeau and Gonnelle. The nature of the apparatus used has been alluded to under CHRONOSCOPE; and also, at some length, under LIGHT, VELOCITY OF. The chief results are the following:—Mr. Wheatstone found that electricity, can travel at a rate *one and a-half times* greater than that of light: in other words, "that the electric spark would go round our globe between seven and eight times in one *second*." According to Fizeau and Gonnelle (whose results are virtually confirmed by Mr. Mitchel of Cincinnati), the beginning of an electric current may be transmitted along a copper wire at a velocity which is not greater than *three-fifths* the velocity of light.

Still greater discrepancies are shown by extensions of experiments, with the same object in view, to varied circumstances of insulation and length in the conductors experimented on. For instance, trials in Queenstown Harbour, in July, 1856, when the two portions of the first Atlantic cable, on board H.M.S. Agamemnon and the U.S. steam frigate Niagara, were for the first time joined into one conductor, 2,500 statute miles in length, gave about $1\frac{3}{4}$ seconds as the time of transmission of a signal from induction coils, through that length; corresponding to a velocity of 1,400 miles per second. The following table contains some of the chief results hitherto published as evaluations of the "velocity" of the transmission of electricity:—

	Miles per second.
† Wheatstone in 1834, with copper wire,.....	288,000
† Walker in America with telegraph iron wire,	18,780
† O'Mitchell, ditto, ditto,	28,524
† Fizeau and Gonnelle (copper wire),	112,680
† Ditto, (iron wire),	62,600
† A. B. G. (copper) London and Brussels telegraph,	2,700
† Ditto (copper) London and Edinburgh telegraph,.....	7,600
Induction coils through 2,500 miles Atlantic cable, tested by heavy needle galvanometer, Queenstown, 1857,.....	1,430
Daniell's battery through 3,000 miles Atlantic cable, tested by mirror galvanometer, Devonport, 1858,	8,000

Now it is obvious, from the results which have been quoted, that the supposed "velocity" of transmission of electric signals is not a definite constant like the velocity of light, even when one definite substance, copper, is the transmitting medium, but is largely influenced by the circumstances in which the conductor is placed, being, for instance, much greater when the wire is insulated in air on poles than when it is surrounded by

gutta percha and iron sheathing, and either submerged, or in coils as on board ship. Further, it is to be remarked that even in conductors, in precisely similar lateral circumstances, the apparent "velocity" is greater the smaller the length of the conductor used. Lastly, we may allude to the fact that some experimenters and writers have maintained, that the velocity of the transmission of electric signals differs with the source of excitation; being on the whole greater, the more intense and sudden is the electric impulse applied; while, on the highest authority, it has been maintained that the velocity of transmission is quite independent of the intensity of the source. Among all these discrepancies between the statements of careful experimenters and writers of high intelligence, how is the truth to be under-

* Through some misapprehension, Mr. Delmann himself has not perceived that his own method of observation really consists in removing a portion of the earth, and bringing it insulated with the electricity which it possessed *in situ*, to be tested within doors, otherwise, he could not have objected, as he has, to Peltier's view.

† Liebig and Kopp's Report, 1850 (translated), p. 168.

‡ Athenæum, 14th January, 1854, p. 54.

stood? We cannot doubt the general accuracy of their results; and if their statements and conclusions are contradictory, we may be sure that an explanation is to be found in a comprehensive theory of the subject. It would carry us much beyond the limits of the present article to do more than sketch very slightly the chief points of electro-dynamic theory which are involved.

In the first place, it must be considered that three properties of electricity, in the present state of science not understood except as quite distinct from one another, are concerned in the transmission of an electric signal along an insulated conductor:—(1), "Charge" or electrical accumulation in a conductor subjected in any way to the process of electrification. (2), "Electro-magnetic induction," or electromotive force excited in a conductor by variations of electric currents, either in adjacent conductors or in different parts of its own length. (3), Resistance to conduction through a solid. We may illustrate these three properties of electricity in an elongated conductor, such as a telegraph wire, by considering their hydrodynamical analogies for water in a canal or in a tube:—(1), Accumulation of a greater or less quantity of water in any part of the canal or tube. (2), Inertia of the water. (3), Viscosity or fluid friction. If the first did not exist, as would be the case if the water were incompressible, and if it were inclosed in a perfectly rigid channel or tube, completely filled by it, the velocity of water flowing along the canal would necessarily be the same throughout its length. In these imaginary circumstances, if a piston is pressed into the tube at one end, the effect in moving the water must commence simultaneously along the whole length, and the velocity of transmission of a water pressure signal must be infinite (although, of course, the maximum strength of current producible by the force applied cannot be acquired in an instant, because of the inertia of the water). But, in reality, water is somewhat compressible, and therefore, even in a perfectly rigid tube, the immediate consequence of pushing forward a piston at one end, is to cause a condensation, and therefore accumulation of water in the near parts; and, according to the dynamical theory of sound, the first effect only reaches a distant part of the tube after a finite time, corresponding to a constant velocity, called the velocity of sound, which depends solely on the compressibility and the inertia of the fluid. If the tube inclosing the fluid, instead of being perfectly rigid, be, as every real substance is, to a greater or less degree, somewhat compressible, the transmission of an impulse will be modified—in general retarded—and to a very great degree, if it consist of such a substance as India-rubber, when the compressibility of the water itself will not come sensibly into play, and the first appreciable impulse, received at the remote end, will come in a time depending on the inertia of the fluid and the lateral yielding of the

tube, and corresponding to a velocity much inferior to that of sound in the fluid itself. Nearly the same law of motion will be followed under the influence of gravitation, instead of elasticity, by water in a canal, when a quantity of water, not enough at any time to increase or diminish the depth of the canal in any part by a difference considerable in proportion to the whole depth, is admitted or drawn off from either end. If, lastly, the viscosity of the fluid is taken into account in any of these cases—and if, to make the law of resistance to the motion of the fluid through its channel be the same as that of the resistance to conduction of electricity through a solid wire, we suppose the whole interior of the channel to be filled with porous or spongy matter, or to be closely set with transverse barriers, filled with minute apertures, the hydro-dynamical problem presents precisely the same elements for a mathematical calculation of the results, and the law of motion is expressed by the same partial differential equation as we have in the electrical problem to determine the laws of the transmission of electric signals through telegraphic lines, either extended on poles through the air, or insulated under the sea in the usual manner of submarine cables. In a line insulated in the air on poles the electrostatic capacity is extremely small, and the transmission of signals follows laws agreeing closely in character with those of the transmission of pressure impulses through water or air contained in a long rigid tube. Accordingly, a definite velocity of propagation of electric impulses, depending on the inertia and the capacity for charge, is to be looked for, as has been done in a first article, published by Kirchof, on the subject; and a law of extinction, identical with that of sound in a rigid tube, when sensibly influenced by the viscosity of the fluid, will be required to complete the theory by expressing the effect which resistance to conduction produces on the motion of electricity through the wire, as the same able mathematician has found in a subsequent investigation, recently published. This theory points to a velocity of propagation for electric signals in a telegraph wire considerably greater than that of light, and is so far in accordance with Wheatstone's observation; but it must be admitted that the foundation is incomplete on one important point—the electro-magnetic induction which determines what we have called the "electric inertia;" and until this lacuna is filled up, it cannot be considered that we have a precise determination of the velocity of an electrical impulse, or of the time of an electrical oscillation through a telegraph wire in any circumstances. That it must be so great as not sensibly to contribute to the retardations of signals, or in any other way affect the practical working of submarine lines, is a fundamental assumption made by W. Thomson in his mathematical theory of the submarine telegraph, and justified by the fol-

lowing considerations:—(1), That any agency depending on electric inertia must give rise to retardations and certain other effects, in simple proportion to the lengths of line used; and therefore, that if any such effects bear a considerable part in the remarkable phenomena observed in signalling through submarine lines of 800 miles and upwards in length, they must, in lines of shorter length, give results very different from those actually observed. (2), That the character of the phenomena actually observed in submarine lines presents no feature attributable to electric inertia. (3), That a mathematical investigation, not yet published, showed that mutual electro-magnetic induction between the different conductors either of an ordinary multiple wire cable (in which the gutta percha coats of the different wires are each moistened all around by the sea water), or of a cable with two or more wires insulated in one continuous mass of gutta percha, and consequently electro-magnetic "inertia," in a single submarine conductor, cannot be sensible in comparison to what he called "peristaltic induction,"* if the length of the line be more than one hundred miles; although in lines of ten miles or less, effects of the former class, being in proportion to the length of the line, may actually preponderate over effects of the latter, which are in proportion to the square of the length of the line.

The theory founded upon this assumption, excluding the second of the three properties of electric action mentioned above, must of course rest on the first and third; and its fundamental principles are therefore the law of charge and the law of conduction. The retardations which it shows (depending on slowness of viscosity, not slowness of "inertia") follow the law which Fourier long ago discovered in his beautiful mathematical theory of the conduction of heat through a long bar (the "linear propagation of heat"). Thus an instantaneous application of electromotive force at one end of an indefinitely extended line, gives rise to a long gradual swell, and still more gradual subsidence, of electric current through any distant part of the conductor, the instant when the maximum strength of this current, or its maximum rate of increase, or its maximum rate of diminution, or when any stated proportion of the maximum is reached by the rising or falling flow at any point of the line, is later than the time of the initial impulse by an interval increasing in proportion to the square of the distance from the origin. The beginning of the current is instantaneous all along the line, according to this theory;—is in reality delayed only by electric inertia, and that not at all sensibly, and is practically observable after a smaller and smaller interval, the more sensitive the instrument employed to detect it.

Thus, in Queenstown Harbour, in 1867, the

ordinary telegraph galvanometers and relays employed in observing the transmission of signals through the 2,500 miles of cable on board the two ships, gave their indications after a retardation of $1\frac{1}{4}$ seconds from the instant of the application of an electro-magnetic impulse at the remote end. At Keyham, in 1858, before the cable was again taken to sea, a quicker and more sensitive instrument—Thomson's mirror galvanometer—gave a sensible indication of the rising current at one end of 8,000 miles of cable about a second after the application of a Daniell's battery at the other.

Observations with the same instrument, or with different instruments of the same degree of sensibility, and with coils presenting no sensible resistances in comparison with the whole resistance in the line, would, if the insulation of the line were perfect, show retardations proportional to the squares of the distances travelled over by the impulse, provided the battery power is varied in simple proportion to the distance. In other words, the "velocity" of propagation might be said to be inversely proportional to the distance travelled. A rigorous verification of this law cannot be obtained in practice, because perfect insulation is unattainable; but one striking fact, alluded to above, is clearly explained by it—that, on the whole, the greater the length of line used, the less has been found the apparent velocity.

With reference to the velocity of propagation of regularly continued periodic impulses, whether from battery or from induction coils, applied at one end of a long submarine wire, the mathematical theory has given results identical with those which Fourier found in his investigation of the propagation of the summer heat and winter cold into the earth; and it thus appears that, in a telegraphic line of indefinite length, with a regular harmonic variation of potential applied at one point—(1), The retardations of maxima, of zeros, and of minima of potential and of current, are in simple proportion to the distances along the line. (2), The magnitudes of the effect diminish in geometrical progression, at equal intervals of greater and greater distance along the line. (3), The velocity of propagation of the phases mentioned in No. 1 is inversely proportional to the square root of the periodic time.

For further information on this subject, see ELECTRIC TELEGRAPH.

ELE

Electric Light. The light termed Electric, manifests itself under two sets of circumstances:—
 First, if a conductor be charged to a state of over-tension, a disruption or discharge takes place, accompanied by a snap, crack or less loud. This is easily illustrated by the Leyden jar. This spark varies in colour and character according to the medium through which the discharge takes place, be that atmospheric air or any other gas, and it varies also with the metals of which the conductor and the body receiving it are composed. Secondly, from the terminals of the wires from the two poles of a galvanic arrangement a succession of sparks as quick as to appear a continuous stream, may be obtained, provided the arrangement be powerful. Thin wire placed between the terminals may be raised to a white heat, or even melted, and if these terminals be connected with pieces of any inflammable substance—any of charcoal, combustion takes place, accompanied by the evolution of light of astonishing splendour. Wurmman produced an illumination in this way, in one of his experiments, equal to that of 800 gas jets. Bunsen computed that in one of his, light was evolved equivalent to that of 572 candles, and Fresen and Foucault—employing 46 elements of Bunsen's pile—elevated the light to an intensity of about one-third or one-fourth that of the unclouded sun. Now the highest brilliancy ever produced by the Drummond light, or the combustion of lime in a jet of oxygen and hydrogen, is only about the hundred and fiftieth part of that proceeding from our luminary. Considering that the expense required to evolve this extraordinary illumination is really trifling, one cannot be surprised at the existence of a general and strong desire to turn it to economic use. A mechanical

ELE

difficulty stood at first in the way, originating in the waste of the charcoal. But means were found to move one terminal, so that the charcoal points might be kept at a uniform distance. The *Regulators of Starks and Petrie* in this country, of Acherson, Foucault, Breton, and, best of all, of Dubouq, in France, are all that can be desired; but the ordinary use of this light is forbidden by its very splendour. It quite dazzles every one near it, and can be endured only at a considerable distance. It will never therefore be applied to light up our houses or streets, but it would be invaluable in lighthouses.—Let us proceed, however, to a scientific analysis of the Electric Light. This analysis, as already hinted, must consist of two parts—an analysis of the Electric Spark, and an analysis of the Light produced by *Currents*. Of course the instrument of analysis is the prism; we must examine the electric spectra, exactly as we do the spectrum yielded by a solar ray.

I. THE ELECTRIC SPARK.—The spectrum yielded by the electric spark consists of two spectra overlapping each other—one belonging to the gas through which the spark passes, and the other to the metal of the conductor. The two are easily separated by varying the conductor while the gas or air remains the same.

(1.) The spectrum that is independent of the metal of the conductor, is like the solar spectrum traversed by a great multitude of lines, which, however, are the reverse of Fraunhofer's, inasmuch as while the latter are dark lines, the former are brilliant ones. The comparison between the two spectra will be made more easy by aid of the annexed diagram executed by Angström, in which they are placed side by side—the upper being the electric spectrum. The luminous lines have the colour of the space in the

Fig. 1.

quartz to which they belong.—On inspecting these two spectra, a general resemblance is apparent—sufficient to convince one that the explanation of the dark lines must carry with it in solution an explanation of the bright lines also; nevertheless there is very little coincidence of individual bands. Such lines as C, D, E, G, and also H, in the electric spectrum, nearly correspond with those in that yielded by the solar ray; but to the two electric bands which far exceed all the others in brightness, viz., γ and λ , there is no dark analogue whatever.—The electric spectrum, figured above, is that evolved from a spark passing through our common atmosphere; but on every account it would be interesting to know what occurs in the case of its passing through different gases. We are indebted to Angström

for another diagram, illustrating this part of the inquiry, which we also subjoin.—These diagrams

Fig. 2

are exceedingly curious and suggestive. It will be seen that some of the brightest of the lines in

the air spectrum disappear from the oxygen one, and reappear in that yielded by the spark passing through nitrogen. The hydrogen spectrum is exceedingly peculiar, and to render it more definite, Angström places a waving line below, indicating the degree of the illumination of each bright region.—One general remark, we think, may be hazarded, as fairly deducible from these appearances, viz.:—the whole phenomena must have a close relation to the aeriform bodies through which the dispersed light passes; so that the theory of Fraunhofer's dark lines ought to be sought for in actions of the Earth's atmosphere, and of the atmosphere of the Sun.

(2.) The second spectrum, or that derived from the combustion of the metallic particles carried from either pole by the electric discharge, and often, if not always volatilized, is an exceedingly curious one. This spectrum does not yield complete transverse lines, but only parts of such, appearing to proceed from both edges of the prism, and becoming extinguished before they reach the centre. Each metal has lines peculiar to itself. One or two lines, indeed, such as *n* and *m*, seem common to all the metals, but on the whole they are very independent of each other. Wheatstone—to whom this class of researches is very largely indebted—observed, that when the poles are formed of different metals, the spectrum contains the lines of both; and when a chemical composition of two metals is employed the spectrum also yields the lines of both, and not a new system.—It were useless to speculate, in our present state of knowledge, on the causes of these most curious appearances.

II. LIGHT FROM THE ELECTRIC CURRENT.—The best mode of studying the phenomena of this species of electric illumination, is through its manifestations in the ELECTRICAL EGG (*q. v.*), or vacuum tubes. There are two sets of circumstances here also that merit attention.

(1.) The student who has read the article just referred to, will recollect, that around the two poles, lights of different colours are collected during the discharge—a light of fiery red adhering to the positive pole, while—separated from the red light by an obscure space—a blue tinge envelops the negative or warmth pole. Neither of these lights are homogeneous, as may be readily proved by the method of absorption; but Dové of Berlin appears to have first thought of studying them by aid of their spectra. He easily disposes of the idea that any differential phenomena can, in this case, be due to peculiar collections of gases around these poles; for when the poles are altered on the instant by the commutator of Rhumkorff's machine, the spectra change with them. The following are the appearances he witnessed:—The current being passed through a pear-shaped Geissler tube, in which the electrodes are platinum points, the spectrum of the blue light showed a large black streak in the blue, a second similar one at the limits of the blue

and green, a very small streak at the limits of the yellow, and nothing in the red. The light at the positive pole gave a crimson violet and blue band, several small streaks in the green, a very black streak at the limits of the yellow, and a small dark streak in the middle of the red. Changing the tube for one of another shape, the spectrum of the blue light remained unaltered, but in the positive spectrum two additional small dark streaks appeared within the blue band. If brass electrodes (points) are employed in the common electrical egg, the phenomena are altered in a very few particulars only, viz.: the negative spectrum displays no new bands, but between its two broad bands the light appears greenish; and a few more bands appear in the blue of the spectrum of the red. Substituting a ball for a point at the negative pole, it seemed as if the two lights came to contain a portion of each other; nevertheless in every case the spectra remained different and distinct.—Dové does not attempt to speculate concerning the causes of these singular appearances, but he suggests a valuable practical application of them. It has long been a favourite conjecture, that the northern aurora is really due to electric currents passing through a highly attenuated atmosphere—the fiery red at the positive pole of a vacuum tube intimately resembling the red which characterizes many auroras. “Now,” says Dové, “the peculiarities presented by the electric light *in vacuo* are so marked, that it appears easy to decide definitively by prismatic analysis, whether the light of the Aurora borealis is or is not of an electrical nature.” An assimilation, to a certain extent—not precisely as Dové indicated—has been accomplished by Dr. Robinson, of Armagh. Under article ELECTRICAL EGG we have noticed the marked presence of fluorescence in the light produced by electric discharges. Dr. Robinson writes as follows:—“On the occasion of an aurora of more than average brightness, on 14th March, 1858, I availed myself of the opportunity to try whether this light was rich in those highly refrangible rays which produce fluorescence, and which are so abundant in the light of the electric discharges; and I found it to be so. A drop of desulphate of quinine on a porcelain tablet seemed like a luminous patch on a faint ground; and crystals of platino-cyanide of potassium were so bright that the label on the tube which contained them (and which by lamp-light could not be distinguished from the salt at a little distance) seemed almost black by contrast. Their effects were so strong in relation to the actual intensity of the light, that they appear to afford an additional evidence of the electric origin of the phenomena.”

(2.) The spectra produced by the light evolved by the current passing through rarefied gases that show the stratifications, have been recently examined by Plücker. They are exceedingly brilliant, and differ wholly from those belonging to the electrical arch of light in the air, or in

gases of ordinary density. They are besides so distinctive, that Plücker sees in them the surest mode of determining which gas it is that remains in the tube. The Geisler tube used was one of a peculiar shape. In length above two feet, it had in the middle an ellipsoidal or cylindrical widening. The ends through which the platinum electrodes passed, were wider and shorter cylinders; and these were connected with the middle piece by two tubes of different diameter, the narrower being a rather wide thermometer tube. In the spectra, from this tube and all others, the dark intervals of the stratification are of course changed to longitudinal ones, traversing all the colours of the spectrum; and every such spectrum differs from the ordinary solar spectrum in this,—the colours do not merge into one another. On the contrary, they are sharply demarcated; and the separate spaces of colour are also divided into well defined lighter and darker stripes. The following are Plücker's notes concerning the spectra from these stratifications, as manifested by attenuated hydrogen, oxygen, and fluoride of boron:—1. *Hydrogen* gave a comparatively simple spectrum, in which five bright bands of almost equal breadths were prominent;—A, a bright violet band beyond the limits of the spectrum; three bands in the green, of which one, B, bounded the green towards the violet, D forming the boundary on the other side, and C between these last about twice as far from B as from D; finally, a beautiful yellow band, E. The order of intensity of the bands in the green is D, C, B, D being the brightest, and of a yellowish tinge. The red is very prominent; a thick black line occurs near its farther boundary; it is separated from the yellow band, E, by another broad black band. D is separated from E by a broad gray interval. The violet light is confined to the band A. The space between A and B is divided into a completely black space, and one of an indefinite dark colour. The black space sharply bounding band A is three times as broad as a third of the whole space between A and B, or between B and D.—How far is science as yet from being entitled even to venture a guess concerning the causes of such phenomena!—2. As to *Oxygen*, other puzzling circumstances occurred during the scrutiny of its spectrum. A pale pink coloured light in the narrow part of the tube gave a remarkably bright band at the end of the red, and two beautiful orange coloured bands, separated by a narrower and a perfectly black one. In the green, bright bands appeared; the violet was very dark. *But the spectrum began to change.* The violet grew more intense, black streaks appearing in it, and the bright line to which the red was originally confined became paler and paler. Bright red bands appeared over a wider space alternating with dark ones. By increasing the power of the induction current, the spectrum was rendered constant for a short time, but it soon began again to change, dimi-

nishing rapidly in intensity; while the light in the narrow tube passed into violet. The discharge grew discontinuous, and finally the current *entirely ceased* to traverse the tube. The spectrum first seen was clearly that due to attenuated oxygen, and these changes must have been owing to its gradually losing its free condition under continued electric influence. Perhaps it may have first passed into ozone; at all events, in the end the tube behaved as a non-conducting vacuum.—3. The spectrum of gaseous *Fluoride of Boron* differs greatly from both the former, and is exceedingly beautiful. While it shows bright colours throughout, *red* together with *orange* and *yellow*, takes up about a fifth of the whole space: of the other four-fifths, two are occupied by the green, the remainder by the violet. There is no apparent transition from the violet to the green—the blue seeming entirely wanting. Yellow and orange form two sharply bounded bright bands of about equal breadth, both together being about half as wide as the red;—from this latter the orange is separated by a strong black line. Near the boundary of the red there is a second great black line. The space of the red between these two black lines is divided into six equal parts by five *fine* black lines; and on the other side of the strong black line first mentioned, there is in the orange and yellow also the same number of fine black lines, at the same distance from one another. In the green, about twice as far from the violet as from the yellow boundary, there is a bright green band, about as broad as the yellow band. This green band divides the green space into two parts, which differ importantly from one another. That part which lies next the yellow has a bright shining band in its middle, and the green on either side of this band is not uniform, but becomes gradually darker towards its extremities. The remaining portion of the green and violet have quite a characteristic appearance. This space seems divided into *sixteen* bands, *ten* of which belong to the violet. Each separate band is brighter towards the red, becoming gradually darker in the opposite direction. These bands are broadest towards the middle of the violet. The broadest of all is on the one side of a bright shining violet; on the other side it is completely black. At this part, the spectrum presents to the telescope the appearance of a strongly illumined fluted column.—The three spectra now described are essentially different from those belonging to the electrical arch of light in the air, and from metals glowing and burning in it. The electrical arch of light in the air is never free from matter (carbon or metal), whose incandescence gives rise to new bright lines in the spectrum; but Plücker thinks, with evident justice, that the varied appearances described above are closely connected with the chemical constitution of the attenuated gases. He concludes his memoir with the following provocative questions:—

How may the spectrum of a mixed gas be derived from the spectra of its constituents?—How are the spectra of a compound gas related to one another before and after its chemical decomposition by the current?—How does the chemical combination which the gas effects with the electrode, influence the spectrum?—Do isomeric gases give rise to similar spectra?—The student is further referred to these curious memoirs by Plücker; to the original researches by Angström (both of which are reprinted in the *Phil. Mag.*), and to the previous memoirs by Wheatstone. He will find further interesting information of another kind in Feddersen's paper on the Electric Spark, in *Phil. Mag.*, Supplementary No., Jan., 1859.

Electric Light, Stratification of. See ELECTRICAL EGG.

Electro-Chemistry. That electricity possesses the power of effecting chemical changes, may be seen in the instance of the combination of oxygen and hydrogen, when a spark from the common electrical machine is passed through a mixture of those gases. The same thing is noticed in the formation of nitric acid from the constituents of the atmosphere during thunderstorms, and the peculiar odour experienced during the working of an electrical machine, believed to indicate the formation of ozone. These may be given as instances of chemical action produced by the agency of electricity or electro-chemical effects; and the science which treats of them might be called Electro-Chemistry. But this term has more particularly reference to a far larger and more important series of actions, which are produced by the agency of the voltaic current—actions which have been found to be regulated by laws definite and most important in their practical applications in the arts, and also as regards the extension of chemistry itself, both in theory and processes. It is more particularly in effecting separation of the constituents of a compound, or in chemical decomposition that the chemical effects of the voltaic current are manifested. Bodies differ greatly as to the facility with which they yield to the decomposing powers of electricity. Thus, iodide of potassium readily yields to the action of a single pair of small plates, while water requires the application of a battery, and sulphuric acid can scarcely be decomposed even by the most energetic currents. The decomposition of water may be taken as a type of the mode in which electro-chemical decompositions are effected. When the conducting wires from the two poles or electrodes of a battery are immersed in water at a distance of half an inch from each other, bubbles of gas immediately begin to appear on the wires, and rise through the liquid. They may be collected in separate tubes held over the wires, and can be proved to possess the properties of oxygen and hydrogen, and when mixed and exploded, to be capable again of producing water. The quantity

of water decomposed, and, of course, of gases produced, is found to be always proportional to the energy of the current, and may be taken as one of the readiest and best measures of its power. Annexed is a figure of the instrument known by the name of a voltameter, or indicator of the power of a battery. At the upper part of the figure are represented two small brass cups containing mercury, into which the conducting wires of the battery are dipped. From these cups descend, through a cork, two pieces of copper wire, to which are soldered two strips of platinum foil, of one or two square inches of surface. The cork is fitted to a wide-necked bottle, filled with water, to which 1-8th of sulphuric acid has been added. A bent tube to carry off the mixed gases is inserted in the cork. The platinum plates may be about one-fourth of an inch apart. The gases are measured in a graduated pneumatic jar, and the energy of the battery judged of by the volume given off in a given time. The sulphuric acid does not undergo decomposition, but is found greatly to assist the decomposition of the water—probably by promoting its conducting power. Steel plates may be substituted for platinum, if the water be saturated with carbonate of potash instead of sulphuric acid. Proposals have at different times been made to employ the galvanic battery as a mover of machinery, by exploding the gases evolved by it, from water, in a cylinder under a piston, but hitherto no practicable result has followed. It might be expected that, as each molecule of water is composed of oxygen and hydrogen, the decomposition of water would occur at some one point of the interval between the two plates or electrodes, and that the transfer of the liberated gases to the poles might be observed; yet the most minute inspection of the intervening space by microscopic means has failed to detect any such transport or the slightest indication of a current among the particles of the liquid. It is undoubtedly possible, considering how infinitesimally minute we know the ultimate atoms of substances to be, that the decomposition of water may be, at every instant, occurring, not merely at one point of the intervening chain of liquid particles between the two poles, but simultaneously at all the points, and that thus there would be equal and opposite sets of currents of gaseous molecules proceeding towards their respective poles, so that the one series of mechanical effects would counteract the other, and prevent the appearance of a visible stream among the liquid particles. This will not appear so improbable if we remember the excessive

Fig. 1.

number of molecules, which must, from the known minuteness of the atoms of matter, go to form even the smallest visible globule of one of the gases. The absence of any perceptible current between the poles during the decomposition of a chemical compound is generally explained as follows:—Supposing, as before, the case of water, which is composed of oxygen and hydrogen, and that we have a number of molecules whose composition before the current has passed is symbolized in the upper line of letters, and after the

first passage of the current by the lower line. If the two terminal molecules are acted on by the polarity of the poles of the battery in contact with them, and by alteration of their electric relations, the two gaseous molecules of each, separate from each other, the oxygen remaining at the positive pole, and the hydrogen at the negative; but the oxygen at the negative pole, instead of passing across the whole line of liquid to the positive pole, merely by its altered electric state decomposing the next atom of water, uniting with its hydrogen and setting its oxygen free to decompose the next, and so on in succession, thus transmitting a wave of force from one pole to the other rather than a mechanical transference. Indeed it is now believed that the passage of current electricity along any conductor, as, for instance, a wire, consists of this transference of force from one particle to another, or perhaps by a series of decompositions and recompositions in a way somewhat similar to this, rather than by the passage of a fluid, as has so long been the favourite explanation. Substances capable of being decomposed by electric currents are termed electrolytes, and the process of decomposition is often called electrolysis. Binary compounds are separated into their elements, the one passing to the positive pole being called electro-negative, and the other called, with reference to it, electro-positive, going to the negative pole. Salts and Haloid substances are decomposed into their proximate constituents; for instance, a solution of sulphate of soda being subjected to the current, after a short time free sulphuric acid will be found at the one pole and soda at the other. The chief electro-chemical laws which have been discovered are as follow:—The same elementary substance in separating from a given compound always passes to the same pole. The quantity of a compound which is decomposed is proportional to the quantity of electricity which passes. The quantity, by weight, of different compounds which can in the same time be decomposed by the same current is proportioned to the number representing the chemical equivalents or atomic weights of the compounds. Thus 80 grains of sulphate of copper will be decomposed by the same current which will in the same time decompose 9 grains of water, or 58 of common salt. Difficulties are often experienced in tracing

out the direct effects of the current, owing to what are called secondary results, that is, the combination of the liberated substances with the materials composing the poles of the battery, or with others mixed with the liquid. Thus, if in the apparatus for the decomposition of water, the pole where the oxygen ought to appear were composed of an oxidisable substance instead of platinum, as, for instance, zinc, then an oxide of zinc would be formed, and little or no oxygen would appear in the form of gas. This circumstance of the electrodes having an affinity for the newly liberated or nascent elements can be taken advantage of for the production of effects otherwise scarcely attainable, and also for enabling a small battery, or even a single pair of plates, to effect the decomposition of compounds which only yield to exceedingly powerful currents in the ordinary apparatus. Thus the most interesting and important results of Electro-Chemistry, are the decompositions of the alkalies, soda, potassa, and the earths, lime, magnesia, silica, &c., into their constituent metals. This was accomplished by Davy by means of the colossal batteries of the Royal Institution of London, and still requires by the best ordinary arrangements, currents of great energy. The little double-celled apparatus of Becquerel, as modified by Golding Bird, effects the decomposition of the alkalies and earths, and indeed of most other compounds, by the long-continued action of a feeble current, aided by well-chosen affinities, in an elegant and most convenient manner. This little apparatus is represented in the annexed woodcut. A glass

Fig. 2.

cylinder D, 1·5-inch in diameter and 4 inches in length, is closed at the lower end by a plug of plaster of Paris 0·7-inch thick. This cylinder is fixed by means of corks inside a cylindrical glass vessel A, about 8 inches deep, and 2 inches in diameter. A piece of sheet-copper, 6 inches long and 8 inches wide, having a copper conducting wire F, soldered to it, is coiled up and placed in the small cylinder with the plaster bottom; a piece of sheet zinc of equal size is loosely coiled up, and placed in the external cylinder, being furnished with a conducting wire like the other. The larger cylinder being then filled with weak salt and water (common salt), and the smaller with a saturated solution of sulphate of copper,

the apparatus constitutes a small battery, a modification of that known as Daniels' (see BATTERY), which will keep in action for several weeks, and may be used for decomposing such solutions as acetate of lead, iodide of potassium, &c.; but may be made efficacious for more important effects by combining it with the second arrangement, as seen in the cut. The vessels of this are arranged precisely as in the case described, only into the external one is placed a weak solution of common salt, and into it is immersed a small plate of amalgamated zinc (see BATTERY) soldered to the wire coming from the copper of the small cell in the other apparatus. The inner cell is filled with the solution to be experimented on, and into it is immersed a plate of platinum foil, soldered to the wire from the zinc of the other cell. If solutions of the muriatic of tin, zinc, antimony, silver, &c., be introduced into the smaller tube beside the platinum, after a time varying from a few minutes to some weeks, the reduced metal appears on the platinum plate. If a solution of fluoride of silicon, prepared by passing a current of the gaseous fluoride into alcohol, be introduced into the apparatus, the platinum in contact with it in the course of a few hours becomes tarnished, and in a few hours more is covered with a dense coating of metallic silicon, which soon becomes converted into a white powder of pure silica by combination with the oxygen of the air. Metallic potassium and sodium can likewise be obtained from the apparatus, by putting a small capsule of mercury in the bottom of the decomposing cell, and pouring over it a solution of chloride of potassium, and bringing the platinum in contact with the mercury. The metals enter into amalgamation with the mercury, which is afterwards driven off by heat. Under the head ELECTROTYPE will be found some information regarding the practical application of Electro-Chemistry to the arts. And besides these applications, it may be mentioned that it is now extensively useful in the processes of preparing different metals on the large scale from their ores, and also that proposals have recently been made whereby different metallic compounds, such as those of mercury, and lead may be extracted from the living system in cases where they have been introduced as medicine or as poison. Becquerel and others have made an interesting and important use of the chemical action of electric currents in obtaining, by their means, the formations of crystals, many of which had previously been found in nature, but could not be formed by any artificial process, leading to the supposition that the electric currents which traverse the earth may have in many instances been the cause of their deposition. Many of the simple or compound crystals referred to can only be formed by the long-continued action of an exceedingly feeble current. As an example of one of Becquerel's arrangements, the following may be mentioned:—A glass tube, in the form

of an inverted syphon is taken, and a small plug of moist clay inserted at the junction of the two limbs. Into the one limb is poured a solution of bicarbonate of soda, and into the other a solution of sulphate of copper to an equal height. A bent film of sheet-copper is plunged, one end into each solution. After a time, silken crystals of the double carbonate of soda and copper are seen floating in the solution. Such investigations have an obvious bearing on geological speculation.

Electrode. Synonymous with the term *pole* in galvanic arrangements: it is the substance, or rather surface, whether of air, water, metal, or any other body, which bounds the extent of the decomposing matter in the direction of the electric current. See ANODE, ANION, &c.

Electro-Dynamics. This term is applied to that branch of Electric Science which treats of the effects which are ascribed to the motion of electricity as contradistinguished from those due to its mere accumulation as in Electro-Statics. Strictly speaking, many of the effects treated of under the head of Electro-Statics are due to the transference of electricity from point to point, such as the combustion of wires, the luminous and heating effect of the spark, the sensation of the electric shock, and many others. Still, generally, the term Electro-Dynamics is confined to what relates to the Voltaic, Thermo-Electric and Magneto-Electric currents. This science is entirely of modern origin, dating from no farther back than 1790, the period of Galvani's great discovery, and in the interval has extended so rapidly and in so many directions, that it will be impossible in the limited space which can be devoted to it in this work to attempt a complete exposition of all its branches. Under the head BATTERY will be found an account of the means by which electric currents are produced, so we shall here confine ourselves chiefly to an explanation of the laws which govern them, their effects, and some of the practical uses to which they have been put. The world has long been familiar with the celebrated experiments of Galvani, which led to the discovery of the voltaic pile, and the different opinions which were entertained as to the origin and nature of the qualities and powers possessed by this remarkable instrument. Galvani himself entertained the idea, that the new force was nothing else than the nervous influence, or life-giving current, which passed in the metallic circuit, and produced the phenomena brought to light by his investigations. Volta, with keener perception seizing on the fact of the metals in contact being of different kind, attributed the effects of the pile to the action of electricity, which he asserted was rendered free by the contact of the metals. More recent investigators, observing that the powers possessed by voltaic combinations were greater, as the chemical actions accompanying them were more energetic, adopted the theory, that while the newly discovered power was electricity, yet, that

the electricity was not the effect of the contact of the different metals, but was due to the chemical action which accompanied it. Notwithstanding of the many attempts which have been made to construct a rational and consistent theory of the voltaic pile, and while it has been proved that the powers possessed by the pile are due to electricity, it cannot yet be said, that the question regarding the origin of this electrical excitement has been satisfactorily answered. Two theories may be said at present to divide the opinions of Electricians. The one is a modification of that of Volta. It was adopted by the illustrious Ampere, and is still in various degrees in favour with many investigators. Its fundamental hypothesis is, that the elementary molecules of matter possess, inherent in their substance, and inseparable from them, portions of electric fluid. Those of the elements which possess negative electricity, are called electro-negative, and have a tendency to appear at the positive pole of the battery in Electrolytical decompositions; and those that possess positive electricity, or electro-positive bodies, separate at the negative pole. Of the first, or electro-negatives, are Oxygen, Chlorine, Iodine, Fluorine, &c.; and of electro-positives, Hydrogen, the metals, &c. But as elementary bodies do not, except in their nascent states, exhibit electrical properties, it is necessary to suppose that each molecule attracts round it an atmosphere of the opposite electricity to its own, which disguises its presence and prevents the properties of free electricity being observed. Supposing now that two particles of oxygen and hydrogen should be brought into each other's vicinity, the two would be similar to two charged Leyden jars, only that the positive electricity would be in the interior of the one, and on the exterior of the other, and *vice versa*. At moderate distances all electric action would be disguised, but if pressure or other cause of approximation be applied, the two opposite atmospheres might be brought so close together, as to unite in opposition to the disguising power of the fluids belonging to the interior molecules, then the atmospheres being rendered neutral could no longer disguise the action of the opposite electricities of the molecules themselves, which would then unite, and if equal quantities of electricity was possessed, each would be rendered neutral, or if the quantities were unequal, might have an excess of positive or negative fluid, which would attract round itself an atmosphere. This theory further assumes, that by the contact of different substances electricity is rendered free, and the tension of this free electricity, constitutes what is called the *Electro-motive force* of the combination, and that the accompanying chemical action is only a result of the electro-motive force. Thus in the case of the ordinary voltaic pair, consisting of copper and zinc with acidulated water between them, the contact of the acid with the zinc gives rise to an electro-motive force, by which the

positive electricity is impelled towards the zinc, while the contact of the acid with the copper, produces an electro-motive force, which accumulates negative electricity in the copper, and these two forces thus conspiring, the metals are put into states of opposite electric tension, which state is imparted to the wires in contact with them. This tension, though in all cases feeble compared with the manifestations of frictional electricity, yet can be clearly evidenced by the electroscope. If we now suppose the two wires to be introduced into a substance such as water, consisting of a combination of an electro-positive and an electro-negative molecule, the negative pole will attract the positive molecule, viz., the hydrogen, and if its tension be strong enough, will separate it from the oxygen, and at the same time communicate to it as much negative electricity as to form its atmosphere. The hydrogen, therefore, in a neutral state, will escape from the combination as free gas, while the particle of liberated oxygen, being still in an undisguised negative state, will act on the nearest molecule of water, and being assisted by the repulsion of the negative pole, will effect its decomposition uniting with its hydrogen and setting free its oxygen, which effects a similar decomposition on the molecule in its vicinity, and so on along the whole line of molecules between the poles, till at last a molecule of oxygen appears free at the positive pole from which it derives positive fluid to form its atmosphere and escapes as neutral gas. According to this view the passage of electricity along a compound chain of molecules capable of decomposition consists of a series of compositions and decompositions along the line from particle to particle, and not of the transport of one particle from one pole to the other. In the same way the passage of the current along a line of homogeneous particles, such as a metallic wire, consists of a similar series of electrical transferences: thus the atoms of copper, being positive, are surrounded with atmospheres of negative fluid, and the whole chain of particles is in a state of equilibrium from the disguising power of the equal quantities of the two fluids; but when a voltaic pole is put into communication with one end of the wire, say that it is the positive pole, it will attract the atmosphere from the particle of copper, which will thus be left free and positively excited to act on the atmosphere of its next neighbour, of which it will partially deprive it, rendering it in its turn active to act on the next, and so on along the whole line of particles till the last, which will be left in a state of positive tension, or in other words, partially deprived of its disguising atmosphere. In this state it would remain, and the whole wire would be in a state of tension, but if the negative pole be applied to the last molecule this tension will be instantly relieved by the communication of the requisite quantity of negative fluid to form the atmosphere, and thus the same series of

actions may recommence and so on continuously constituting the current. The same result would ensue were we to suppose the commencement of decompositions to have occurred at the negative pole of the battery. We have seen that the result of two oppositely electrical particles being pushed into each other's vicinity would be the union of the two atmospheres, and then the attraction of the molecules themselves into close alliance as a compound molecule. It is clear that if the two uniting molecules possessed equal quantities of opposite fluids the compound would itself be neutral and would require no atmosphere or excess of opposite fluid to disguise its electrical state, but if one of the uniting molecules possessed an excess of fluid, then the compound would not be neutral, but would require a partial atmosphere for its neutralization. If we suppose the uniting particles to be of the same kind, that is, both positive or both negative, such as two metals, then the two atmospheres would expand over the united molecules, in an equal degree on each if the two were of equal original tension, but if the one were more positive than the other, as in the case of copper and zinc particles brought into contact, then the atmospheres would pass from the points of contact and expand themselves on each particle, but not in an equal degree nor yet in the same degree as before contact, but in a less degree on the particle of greatest tension: and if the two were removed from contact an excess of atmosphere would remain on the least positive of the two, in this case the copper, and thus the copper having on its particles an excess of negative atmosphere, would be left, after separation, negative with regard to the zinc and to other bodies, giving an explanation of the electro-motive force produced by the contact of heterogeneous substances. According to this view then, the source of the electricity of the voltaic pile is in the electro-motive force developed by the contact of the different substances, and the accompanying chemical action only serves continually to discharge the tension so produced by affording means in the formation of the atmospheres of the new products for the escape of the liberated electricity, so as to allow of the continued development of more by contact, and thus the current or continual charge and discharge is kept up. The other view, to which allusion has been made, regards the chemical action as the cause of the development of the electricity. Be this as it may, it fortunately happens that the laws which regulate the strength of the current when the electro-motive power has once been produced have been ascertained in a precise manner, and are independent of either theory. These laws have been named the laws of Ohm, after their discoverer. Before Ohm's investigation, it had been noticed that the efficiency of a current in producing any of its characteristic effects, such as deflecting a magnetic needle or producing chemical action, was enfeebled more and more as the

conducting wire of the circuit was longer, but yet it could not be precisely stated that the strength of the current was less in the same proportion as the wire was lengthened. Ohm first took into consideration the resistance not only of the wire but of the materials of the pile or battery itself, and taking care properly to estimate each of these, he found that the law could be exactly stated that *the force of the current was inversely proportional to the sum of all the resistances*. As may be supposed also, the force of the current varies according to the energy of the source of electricity itself, that is to the nature and the activity of the galvanic combination. Thus if E be taken to denote the energy of the source of the current or the electro-motive force, and R to represent the whole resistance encountered by the current in the circuit, then F , the force of the current, will be denoted thus

$$F = \frac{E}{R}$$

F denotes the efficiency of the current to produce magnetism or chemical action or heat or any of its other effects, and is called the force of the current. E , or the electro-motive force, does not depend on the size of the plates of the battery but denotes its state of activity, which will of course vary according to the combination employed and the strengths of the liquid solutions, but would be as great for any plate, however small, as for the largest possible. R , the resistance, includes the resistance of the wires, the interposed liquid, if such be included in the circuit as in the voltameter (see ELECTRO-CHEMISTRY), and the resistance of the metals and the liquid of the battery itself. This resistance of the battery can be ascertained in any case by experiment. It is found that this portion of the resistance is diminished by increasing the size of the plates, and in exact proportion as the surface is increased; so that in this way large plates, though they do not increase the electro-motive force, yet greatly contribute to the force of the current by diminishing the resistance. At least this is the way of expressing their manner of action, and it answers perfectly in calculation. In regard of the wire, experiment proves that by doubling the length the resistance is doubled and the current proportionally enfeebled; by trebling the length the current is diminished in a threefold degree, so that the resistance of the wire is directly as the length. Experiment also proves that a wire gives a more energetic current the thicker it is, and exactly in proportion as the wire is rendered thinner the current it conveys from a given battery is enfeebled, so that the resistance of the wire is inversely proportional to its section. If we now denote the whole resistance by R , as before, and the resistance of the battery itself by B , and that of the wire by w , we shall have, supposing no other obstacles to be included in the circuit, $R = B + w$.

But κ varies directly as the distance between the plates which we denote by d , and inversely as the surface of the plates s , and we may put

$\kappa = \frac{d}{s}$ Again w varies directly as the length of the wire, and inversely as the area of its section, it may therefore be represented by $\frac{l}{s}$,

when l is the length of the wire and s its section. If now we introduce these values of w and κ into the formula for F , we shall have F expressed in terms of the elements upon which it depends, giving

$$F = \frac{\kappa}{\frac{d}{s} + \frac{l}{s}}$$

From this formula it is obvious that we can increase the force of the current by increasing the thickness of the wire or diminishing its length, or, if these be not practicable, by increasing the surface of the plates of the voltaic elements or diminishing the distance between them, or lastly, by increasing κ by employing more energetic elements. The formula just given which embraces Ohm's laws, serves for predicting the effect of changing the length or thickness of the conducting wire or varying the size and distance of the plates of a voltaic pair in any case where we keep to the same kind of element and conducting wire; but if we wish to construct a formula which shall enable us to calculate the effect of one voltaic element or conducting wire from those of another, then we must introduce two other symbols which may be replaced by the real quantities which they denote as determined by experiment. These are the resistance of the particular liquid used, which we shall denote by Λ , and the specific resistance of the kind of metal forming the circuit, which we may denote by m , then we shall have

$$F = \frac{\kappa}{\frac{\Lambda d}{s} + \frac{ml}{s}}$$

The resistances of different metals are of course inversely proportional to their conducting powers, which may therefore readily be got from the following table of conducting powers:—

Mercury	100
Iron	650
Platinum	855
Copper	3840
Gold	3960
Silver	4000
Palladium	5790

It will thus be seen that a similar thickness and length of copper wire would enfeeble a current of electricity much less than one of iron; and from what has been said above, it is evident that to get, with the same length, as strong a current from a given battery by means of an iron wire, as a copper one, we would require to use an iron wire of greater section than that of copper in the

ratio of 3840 to 650 or nearly 6 times as great, which if the wires were round would be given by a diameter nearly $2\frac{1}{2}$ times as great. The formula just given applies to the case of a single voltaic pair, and must be modified in order to be adapted to the calculation of the force of a battery composed of any given number of such pairs joined together in the manner described in the article BATTERY. It is evident that as each pair contributes its own electro-motive force to the current, the whole electro-motive force will be proportional to the number of pairs, so if we denote by n the number of pairs, then the whole electro-motive force will be $n\kappa$, where κ represents that of a single pair and all are equal. Although the electro-motive force be n times as strong the current will not be n times as forcible, because the resistance is also increased, the current now having to move through the whole liquid of the different pairs, which will be n times as great a resistance as the liquid of one pair. For a battery, then, the form for the force of the current will be

$$F = \frac{n\kappa}{\frac{n\Lambda d}{s} + \frac{ml}{s}}$$

This will serve in all cases, where the force of a single element or pair is given and the length of conducting wire, to determine the force of a battery of any number of pairs. In compound circuits, that is where the conducting wire is composed of different thicknesses or of different metals joined together, it is found that the force of the current is everywhere the same. It is convenient to refer all resistances of wires or liquids or other matters through which the current passes to certain definite equivalents on a specific standard; this is generally taken at so many units of length of a standard copper wire of specified thickness. The length of this wire, or the number of units of length of it, which afford the same resistance as any conductor, is called the reduced length of that conductor. If we represent the length, conducting power, and section of the substance forming the circuit by l , c , s , and the reduced or equivalent length of the standard wire by l' , its conducting power and section being c' and s' , then, as the force in each case is represented by

$$f = \frac{cs}{l} \text{ and } f' = \frac{c's'}{l'},$$

and it is required that the force of current given by the one is to be equal to that given by the other, we must have

$$f = f' \text{ or } \frac{cs}{l} = \frac{c's'}{l'} \text{ or } l = \frac{c's'l'}{cs}$$

By this means it is easy to find the reduced length of any given length of any wire, and in the case of a compound conductor it is only necessary to calculate the reduced length of each

part and add the whole together to have the equivalent length of standard wire which, were it substituted for the given circuit, would produce no alteration on the force of the current.— Pouillet, Fechner, and Wheatstone have made many experiments confirmatory of Ohm's laws. Wheatstone employs a very useful instrument of his own invention, called a Rheostat, which essentially consists of two cylinders so arranged that it is easy to roll off any length of wire from one to the other and thus introduce it into the circuit, while at the same time its length is measured by the number of turns made by the cylinders. In this way it is easy by means of a galvanometer to value any given resistance in terms of the length of wire equivalent to it, or which, when introduced into the circuit, reduces the needle of the galvanometer to the same position. We can thus readily compare the electro-motive forces of any two voltaic arrangements. It is evident that if the resistance in the one Electro-motor be as much greater than that of the other as the electro-motive force is greater, then the current should have the same force in the two cases, for, in the same proportion as the electro-motive force is greater so it is required to overcome a greater resistance. If π be the ratio of the one electro-motive force to the other, then πE being the one electro-motive force, πE is the other, and if R be the one resistance and πR the other, then

$$F = \frac{E}{R} = \frac{\pi E}{\pi R}.$$

and if by means of the Rheostat a certain known resistance r , in length of wire be added to the circuit whose resistance is R and electro-motive force E , then the force of the current is

$$F' = \frac{E}{R + r}.$$

It is evident that in the other circuit whose resistance has been previously determined, or supposing it to be as much greater than R as the electro-motive force is greater, which is common enough, then if we add by means of the Rheostat a certain length of wire in order to bring the galvanometer needle when acted on by the second current to the same point, and we find this length to be π times as great as that added to the first circuit, the two currents are equal in force, so their expression ought to be equal, and the forces of the currents can only be equal if the electro-motive forces have the same ratio as the resistances. So we have

$$\frac{E}{R + r} = \frac{\pi E}{\pi R + \pi r}.$$

But π is known, and it is the ratio of the electro-motive forces. An exceedingly important principle following from the estimation of the resistances of different parts of the circuit, consists in this, that if the whole

resistance be very great, as in the case of the long wires of a telegraph, then the addition of a large number of coils of a galvanometer wire, or the wire of an electro-magnet, produces very little resistance compared with the whole, and yet by increasing very much the number of turns, we increase in the same degree the power of the current in giving motion to the needles or magnetizing iron without perceptibly enfeebling its force. This may at once be seen from the general formulas for the force of the currents, or it may be stated thus, that though the addition of one mile of wire to a short circuit would make a very great alteration on the force of the current, yet the same length added to a long circuit of 100 miles, would produce very little diminution, hence it is beneficial to multiply the effect on the needles of telegraphs, by employing a great many turns in the coils. By means of the laws of Ohm, we are enabled to resolve, *a priori*, many problems which could not otherwise be accomplished; for instance, in the case that a branch wire is taken from the main circuit so as to cause the current, which passes along the single wire to the point of division, to divide itself into two for the remainder of the course, or for any part of it till the two again join; it is required to determine in all cases of difference of length, thickness, and conducting powers, what would be the comparative force of current in the different parts of such a compound circuit. Let $N D O P$ in fig. 1, be the principal circuit, and $D L P$ the additional one, then $N D$ is called the partial circuit, $D O P$ the circuit of derivative, and $D L P$ the derived circuit. The currents in these parts receive the same names.

Fig. 1.

The current which would pass in $N D O P$ if there were no derived current, is called the primitive current. It is not the same as the partial current in $N D$. The lengths, conducting powers, and sections of the different wires, and the force of the primitive current being given, it is required to determine the force of the partial current, which we may denote by x , the derivative current y , and the derived current z . If the wires have different conducting powers or sections we can reduce them to the same by a formula previously given. Suppose then l to represent the length of the partial current, l' that of the derivative current, and l'' that of the derived current, f being the force of the primitive current. It is evident that we can substitute a wire instead of $D L P$ the derived circuit, which shall be of the same length as $D O P$ the derivative circuit, and which shall produce no alteration on the currents, provided that in the same proportion as we shorten or lengthen the derived wire, we diminish or

ELE

increase its diameter, as this follows from Ohm's law of the resistance. Then to find this section we have

$$s' : s :: l : l''$$

s signifying the original, and s' the calculated section of the derived circuit, giving

$$s' = \frac{l s}{l''}.$$

The two wires, viz.: the derived and the derivative circuit, may now be reckoned of the same length, so the two will be equivalent to a single wire of this length, and of a section equal to the sum of these sections, which will be, if we reckon the sections of the original wire, unity

$$s'' = 1 + \frac{l}{l''}.$$

We can evidently now calculate the reduced length of such a wire, or the length of wire of the original circuit, which might be substituted for it, without altering the current. Its length would require to be greater in proportion, as the section is greater by this law. Hence

$$1 + \frac{l}{l''} : 1 :: l : l''' ;$$

$$\text{giving } l''' = \frac{l l''}{l + l''}$$

This therefore is the length of wire which may be substituted for the divided part of the circuit, without altering the current. It is now easy to calculate the partial current which would exist in the circuit so completed, by joining this length on to the partial circuit. The total length of such a circuit would be

$$l + \frac{l l''}{l + l''},$$

and the force of the current in such a circuit compared with the force in the primitive circuit, would be inversely proportional to their lengths. Hence,

$$x : f :: l + l' : l + \frac{l l''}{l + l''} ;$$

$$\text{giving } x = \frac{f(l + l')}{l + \frac{l l''}{l + l''}} \text{ or } x = f \frac{(l + l')(l + l'')}{l(l' + l'') + l' l''}$$

f being the force of the primitive current. Again, to find the forces y and z , we know that their sum must be equal to the partial current x , and also that z will divide itself between the derived and the derivative circuits, in the inverse ratio of their reduced lengths. The first condition gives,

$$x = y + z.$$

The second, gives

$$y : z :: l' : l''.$$

ELE

These two equations give by elimination,

$$z = \frac{x l'}{l' + l''}$$

$$y = x \frac{l''}{l'}$$

which by introducing the formerly found value of x , gives

$$y = f \frac{l''(l' + l)}{l(l' + l'') + l' l''}$$

$$z = f \frac{l'(l' + l)}{l(l' + l'') + l' l''}$$

x , y , and z , being the forces of the partial, the derivative, and the derived current, and all expressed in terms of the force of the primitive current, and the lengths of the different circuits. It is evident that as l and l' become equal, the force in the derivative and the derived circuit would become equal, as then the expressions for y and z become identical. Under the same condition we find, that the force of the derived and derivative current will be each half the force of the partial current, as the expression for y and z each become half that of x . Again, it is obvious, that as the derivative current disappears the derived current vanishes, because the length of the derivative circuit is a factor of the numerator of the expression for the force of the derived circuit. The latter therefore vanishes along with the former. As an instance of the practical application of these formulas for the forces of derived currents, we may cite the mode, by this means, of arriving very easily and expeditiously at a knowledge of the spot where a rupture of the insulating coating of the wires of a subterranean or subaqueous telegraph has occurred, without the necessity of examining the whole wire piece by piece. To deduce a formula for this purpose from those above given, suppose that a single telegraphic wire only is used, that is to say, that the return current takes place by the earth. Let a current be sent along the wire while a galvanometer is included in the circuit at each end, then it is clear that the galvanometer at the end next the battery will receive the full strength of the undivided current, while that at the extreme end will only experience the effect of the derivative current, the derived current passing through the leak in the coating of the wire at the point of rupture. It is evident that the comparative strengths of these currents will be dependent on the lengths of the circuits, that is, on the position of the point of leakage, or the point of derivation. Let s and s' (in fig. 2) be the stations, and κ' the point of leakage; suppose first, that the battery be placed at s , and let l denote the length of wire intervening between s and κ , l' being the remainder of the wire, and l'' the length of the derived circuit, that is in this case, the length of earth current intervening between κ and the plate

of metal immersed in the ground, as at *s*, and in communication with the battery there. In this

Fig. 2.

case it is evident, that we must add to the mere lengths of these currents the reduced lengths of any additional resistances which may be interposed in the course of the respective currents. These are the resistances the currents experience in passing from the immersed plates to the earth, which, for simplicity of calculation we may neglect, and suppose that the current experiences a resistance r in passing through the leak in the coating of the wire. As the earth offers no resistance to the passage of the current, it is evident, that the derived current only suffers the resistance r , and that this therefore takes the place of l' in the formulas for the forces of the respective currents. If we denote by f the force of the primitive current, or that which would occur were there no leakage, and as before, x and y may denote the force of the partial current acting on the galvanometer nearest to the battery, and the derivative current acting on that at the other end of the wire, we shall have

$$x = f \frac{(l + l')(l + r)}{l(l + r) + l'r} \quad y = f \frac{r(l + l')}{l(l + r) + l'r}$$

$$\text{or } \frac{x}{y} = \frac{l + r}{r}$$

Again, removing the battery to the opposite end of the line and denoting by x' and y' the forces in the galvanometer nearest, and that most remote, we shall have

$$x' = f \frac{(l + l')(l + r)}{l(l + r) + l'r} \quad y' = f \frac{r}{l(l + r) + l'r}$$

$$\text{or } \frac{x'}{y'} = \frac{l + r}{r}$$

By means of these two equations, containing the three unknown quantities l , l' , and r , we can eliminate r and get an equation between l and l' . From the first, we get

$$r = \frac{l'y}{x - y}$$

and from the second

$$r = \frac{l'y'}{x' - y'}$$

Equating these two values of r we have

$$\frac{l'y}{x - y} = \frac{l'y'}{x' - y'}$$

$$\text{or } l = l' \frac{x' - y'}{x - y} \cdot \frac{y}{y'}$$

which exhibits the ratio of l to l' or the proportions of the parts of the wire between either end and the point of leakage in terms of the observed force of the currents.

In experiments which have been made with a view to facilitate and simplify the electric telegraph, it has been found that the earth may be substituted as the return part of the circuit instead of, as was supposed, its being necessary that the complete circuit to and from the distant station should be formed of wire. All that is required is that the battery should have one of its poles connected with a metallic plate buried in moist ground, and that the other pole should be put in communication with a single wire which passes along the line on insulating supports, and after coiling round the electro-magnets or needles at the distant station should be joined to a wire from another plate there buried likewise in the ground. An anomalous fact observed in regard of this mode of completing the circuit is that if the distance between the two plates be small, say a few yards, then the intervening earth seems to present a perceptible resistance to the current, but if the distance between the plates be increased this resistance ceases and the current is as strong as if the earth were not included in this circuit, or had no resistance. This may be accounted for from Ohm's law, that the resistance is inversely as the section of the conductor, as in this case, the section may be regarded as infinite and of course the conducting power infinite or the resistance infinitely small. But whence should it happen that where the earth circuit is short a resistance is experienced? According to Ohm's law of the resistance being inversely proportional to the length, in this case the resistance ought to diminish whereas it increases. In order to the explanation of this circumstance many investigators have adopted the view that the earth does not act as a conductor returning the identical current that passed from the pile, but rather as a reservoir into which the tension of the two poles might be freely and perfectly discharged, thus accomplishing the same end as if the two poles of the pile were joined together by a good conductor, as this mutual discharge, constantly kept up, is what constitutes the current in the conductor. It is said by those who adopt this view that the reason that a short distance of earth intervening between the two poles apparently presents a resistance is, that it is not sufficient to discharge the electricities of the wire perfectly and instantaneously, so that a diminution of the current is thereby caused. Be this as it may, certainly that of this remarkable property of the earth with reference to telegraphic currents is one of the most important discoveries of recent times. Allusion has already been made to the probability of the current being a series of polari-

ties by induction, produced consecutively along the line of molecules of a conductor, and it may easily be supposed that as the exact nature of the actions which give rise to these induced polarities of the natural electricities of the molecules is not ascertained, it would be difficult to deduce precisely the laws which govern the speed with which the current would propagate itself along conductors. Accordingly it is to experiment chiefly that application must be made when the object is to ascertain these laws. As in the case of sound, where for waves of all lengths in the same medium the velocity is the same, so in this case it is probable that in the same substance electric waves of all intensities will travel with the same speed, and also that the time taken to run over a certain space will be proportioned to the space, that is that the velocity will be uniform. These inferences have been confirmed by experiment, yet it does not follow that though the electric impulse or wave should travel with the same speed in circuits of all lengths, yet that the intensity of electric charge necessary to produce a given effect such as making a telegraphic signal, should do the same. It would seem indeed that this is not the case, and that though to transmit an electric impulse along a wire 500 miles would require five times as long as to transmit it 100 miles, yet to raise the 500 miles of wire to the intensity requisite for telegraphic purposes might require much more than five times as long in the one case as in the other, a circumstance that, if true, would exercise a most important influence on telegraphic communication over long distances such as that across the Atlantic. It seems also to be ascertained that the thickness and nature of the insulating envelope, in the case of submerged wire, exercises an influence on the time taken by the electric current in the wire to rise to intensity enough to produce its characteristic effects.

Many efforts have been made both on the telegraphic wires of Europe and America to ascertain the velocity of the electric current in different metals and under various conditions. All observers agree that the velocity is very great, but owing to the vast rapidity, difficulty has been found in making out its exact amount. Mr. S. C. Walker in the following way made many experiments on the telegraphic wires of the United States, and deduced a velocity of from 18,000 to 16,000 miles per second. Two cylinders of metal were placed, one at each end of the wire and metallically connected with it and with one pole of a battery while the other pole of each battery completes the circuit with an electro-magnet, which raises and depresses a steel point against a piece of paper placed on the cylinder each time that the current is passed. The two cylinders are made to revolve with exactly the same speed by clock work, and it will be evident that if an operator placed at each cylinder can by a touch of his finger complete the connec-

tion with the battery and animate each of the electro-magnets so as to cause them to press the steel point against the paper, and if they shall agree to transmit a signal alternately at a given interval, say three seconds, after the signal from the other arrives: now remembering that the transmitted signal registers itself on the cylinder whence it is transmitted as well as on the other, if we denote by a that made by the observer A on his own cylinder and a' that made by him on the opposite cylinder, b and b' denoting the same for the signals made by B , then in the case of no time being lost in the passage of the signal along the wire the following arrangement would be seen on the two cylinders:—

a'	b	a'
a	b'	a

But if a certain amount of time elapse, then the arrangement of the signals on the two papers would not be at equal intervals, but something such as

a'	b	a'
a	b'	a

The difference of distance between $a' b$ and $a b'$ on the two cylinders being the space the surface of the cylinder revolves in twice the time occupied by the current in traversing the wire: Having ascertained this length, which we denote by d in inches, it is easy to deduce the velocity thus. Let c denote in inches the circumference of the cylinder, n the number of seconds occupied in completing a revolution, then the number of seconds spent by the current in rushing along the wire is represented thus:—

$$t = \frac{n d}{2 c}$$

And if l denote the length of the wire in miles

$$v = \frac{l}{t} = \frac{l 2 c}{n d}$$

where v represents the velocity in miles or the number of miles run over in a second. It must be observed that this method takes for granted that the signals can be made at exactly equal intervals, and also that the electro-magnets used to make the impressions either act instantaneously or at least always with the same loss of time, a circumstance that is not fulfilled unless the current should remain of exactly the same intensity. These difficulties can be got over by taking the average of a vast number of results.

MM. Fizeau and Gounelle have employed a different and very ingenious method of ascertaining the velocity of the electric current. Their experiments were made on the Rouen and Amiens telegraphs. They employed two discs of metal fixed upon the same axis, each disc being divided into a certain number of parts at its circumference,

the half of which were filled with pieces of wood or ivory as represented by the dotted lines in the cut. The axis is cut into two parts and united

Fig. 2.

by wood, so as to prevent communications of a current from one disc to the other. One axis is put in connection with a pole of the pile, the other pole put into connection with a metallic plate buried in the earth. A pointed piece of platinum A, presses on the circumference of the disc and has in metallic junction with it the end of the telegraphic wire, the return wire being similarly joined to the platinum point B, which touches the circumference of the other wheel or disc. From the axis of this second disc there passes a wire of a galvanometer, the opposite end of which is in connection with another plate of metal buried in the earth. A and B are so fixed that when the wheel is turned as indicated by the arrow, one of the metallic divisions is leaving A exactly as a metallic division of the other wheel is coming in contact with B. It is evident by this arrangement, that so long as the wheel remains at rest in any position, the current cannot pass, and the galvanometer needle will remain at zero. And the same will be the case whatever degree of rotation be given to the discs, if the current pass perfectly instantaneously along the whole intervening wire, because at no turn is the circuit ever complete, as the points A and B can never be both on metal at the same instant. But if a certain time elapses from the moment the last electric wave leaves A as it passes from the metal, till the same wave arrives at B, then B may have entered on the metal, and may complete the circuit down to the galvanometer. It is further obvious that, as the rotation of the discs becomes more rapid, a greater amount of current may get past to the galvanometer, and that if the rotation be such that the whole of the divisions passes under the platinum while the current is occupied in passing along the wire, then the half of the whole current will pass to the galvanometer, but that if the speed of the disc be increased still more, then the force on the galvanometer will again diminish, as a greater interruption will take place to the current. If then, at the time when the maximum influence is perceived on the galvanometer, the number of turns per second of the discs be observed and denoted by n , the circumference of the disc in inches by c , the number of divisions by m , and the length of the wire by l , v the velocity in miles per second, l being also expressed in miles, is given by $v = l m n$;

for as the whole circumference passes in $\frac{1}{n}$ th of

a second the length of one division, or $\frac{1}{m}$ th of

the circumference will pass in $\frac{1}{m}$ th of $\frac{1}{n}$ th, or

$t = l m n$; but t , the time of one division passing, was also the time of the current running the whole length of the wire, so $t = \frac{1}{m n}$, but

$v = \frac{l}{t}$, so $v = l m n$. In this way it appears

that the electric current traverses iron wire at a rate of 68,000 miles per second, and copper wire at a rate of 111,000 miles per second. The nature of the pile, or its size, exercises no influence on the speed of the current. If, however, what was said with reference to the time required for a wire to rise to different degrees of electric tension, be true, it is evident that these numbers cannot be taken as absolute measures of the velocities of the electric wave, but only as indicating, that, with wires of a certain length and diameter, a force of current, sufficient to affect the needles of the galvanometer, passed throughout this extent at this speed. It is obvious that the subject of the propagation of electric currents in conductors, still remains in much obscurity.

As intimately connected with the theory of the transmission of electricity along conductors, and the velocity of such transmission, it may be well here shortly to allude to the interesting and novel experiments made within the past year by Faraday. These experiments were chiefly made by means of powerful batteries on long lines of immersed submarine telegraphic cable, the wires of which were each coated with gutta percha. He employed an insulated voltaic battery of 380 pairs. The distant end of the telegraphic wire was in communication with a plate of metal buried in the earth, as was also one pole of the battery. When the other pole of the battery was put in connection with the near end of the submarine wire, and the contact then broken, a vivid spark ensued, and if the two wires were held in the hands, the operator received a most violent shock, which continued for some time; by gently touching the end of the submarine wire again and again, it was possible to take away a series of more gentle discharges, though there had been no intermediate connection with the battery. As many as 80 or 40 shocks could thus be got in the same way, as if the wire had continually again the power to charge itself. If some time was allowed to elapse, after communication with the battery had been withdrawn from the wire, before the shocks or sparks were taken from it, they had evidently begun to grow more feeble, but still, after a number of minutes, they were abundantly perceptible. Not only were powerful shocks and sparks got from the submarine wire which had been separated from connection with the battery, but it could inflame gunpowder, and this even for a period

of five or six seconds after the rupture of contact. When a galvanometer was interposed in the circuit between the end of the wire and the earth, after its communication with the battery had been broken, the needles were violently whirled round, even at the end of a period of many minutes.

In other experiments, the galvanometer had one end of its coil fastened to the submarine cable, while the other end was put in communication with the battery, the remaining pole of the battery being still in communication with the soil; in these circumstances, the needles slowly deviated as if the electricity of the battery were pouring itself into the cable. When the battery was separated from the galvanometer, and the latter touched by the finger, or put into communication with the earth, the needle deviated in a contrary direction, indicating an inverse current, or that the electricity which had passed into the cable was returning. The same phenomena were produced, whether the communications of the cable with the earth were broken at one or both ends at the same instant, and they took place at either end of the wire, or with either pole of the battery. A battery of great power was necessary: thus, 12 pairs of plates in a high state of activity produced no such effects. It was also noticed, that a similar cable suspended in the air, produced none of the above described phenomena, though its insulation was as perfect, whence, it would seem, that the water which surrounded the gutta percha envelope was one of the necessary conditions. It is probable, indeed, that the wire and the water, separated as they were by the film of gutta percha, formed a disguising arrangement similar to the armatures and glass of a Leyden jar (see BATTERY, ELECTRIC), whereby great accumulation would occur, the battery serving as a constant source of supply, as if it were an electric machine. On calculation, it was easy to find from the length and diameter of the wires, and their envelopes, that a Leyden battery was thus formed of 1,000 square yards of coated surface. Thus, though the tension of the electric charge could not rise to that of the ordinary electric machine; being no higher than that of the pole of the battery of 380 pairs; still, its quantity was enormous, being the full charge of 1,000 yards of surface.

Several galvanometers were next introduced into the circuit, as, for instance, one at each end of the cable, and one in the middle. It was thus observed, that the galvanometer nearest the battery was affected the instant the circuit was completed, while the one in the middle was some short time in indicating the arrival of the current, and that at the extreme end only showed the presence of electricity after several seconds, and never reached the same amount of deviation as the other instruments. When all the needles were in a state of deviation, if the connection

with the battery was broken off, the nearest galvanometer instantly showed a total cessation of current, the one end of its wire being insulated from the earth, while the other two galvanometers continued for some time to indicate a current, showing that the whole electric charge of the wire was flowing down into the earth by the extreme end of the cable. If, instead of leaving the end of the galvanometer coil which had served for establishing the communication of the whole with the battery free, it be, as soon as it is separated from it, suddenly put into connection with the earth, the whole of the electricity does not then escape by the distant end of the wire, but part of it returns, causing an inverse deviation of the near galvanometer, and exhibiting the curious spectacle of the current passing along the two ends of the wire in opposite directions at the same instant.

Such experiments show that electricity will not freely escape from a wire surrounded by a nonconducting and round that a conducting envelope constituting a condensing apparatus, until so much of the current has entered as to raise its tension to be nearly equal to that of the battery, and that this takes a longer and longer time as the length of wire is greater.

The effects of the electricity may be enumerated as follows:—1st, Chemical; 2d, Thermal or heating; 3d, Magnetic, as evidenced in the mutual influence exerted between a magnetic and an electric current constituting Electro-Magnetism; 4th, Induction, as shown in the induction of magnetism in iron and other similar bodies placed in the neighbourhood of the current, and also in the induction of electric currents in neighbouring conductors. This arrangement is far from faultless, as it by no means embodies all that relates to the current, and some of the subdivisions encroach on and interfere with others, but it serves in some degree as a basis on which to proceed. The first head will be found discussed at some length under ELECTRO-CHEMISTRY.

The wire of an active galvanic battery becomes heated by the passage of the current; and it is observed that the amount of heating rises more rapidly than the power of the battery; that is, that a doubly powerful battery will heat a given wire with more than double effect. It is also noticed, that more heat is produced by a given battery if the conducting wire be thick than if it be thin, and these relations have been stated thus, that the amount of heat produced is inversely proportional to the diameter or the conducting power of the wire, and proportional also to the square of the quantity of electricity which actually passes. It follows that, by increasing the power of the battery, or by diminishing the thickness of the wire, we might get any temperature required, and this is so far practicable that it is easy to attain a white heat in the wire itself besides the development of a

large amount of heat in the battery, as evinced by the whole apparatus rising in temperature frequently to near the boiling point.—It is found that iron and platinum are much more efficacious as heat-producing channels than silver or copper, and, as some say, because they are more imperfect conductors; but, were this the true explanation, then it would follow that silk or gum lac, or glass would be still more efficacious, which is far from being the case. The true explanation no doubt is, that by some peculiarity of structure they are more efficacious in converting the energy of the current, whatever that may be, into the vibratory motion which constitutes heat, in the same way as some substances become more powerfully heated by a blow or by friction than others, by transmitting less of the applied mechanical energy to other bodies, and converting more of it into vibratory motion among the constituent molecules. A pair of plates, on Wollaston's or Smee's principle, of 4 inches square, moderately excited, are sufficient to ignite a steel wire of the thickness used for the hair springs of watches. The arrangement represented in the cut answers

Fig. 4

well for such experiments. A and B are two wires of copper covered with silk or cotton thread, and twisted for steadiness, while the thin wire is stretched between their points. When the poles of the battery are put into communication with A and B, the current passes through the thin wire, which instantly becomes heated to redness, if the battery is powerful enough, or is even dissipated in sparks of oxide by combustion. Gunpowder or other inflammable substances may of course be readily inflamed by being placed in contact with such a wire and the current passed. This fact has been taken advantage of in electric blasting, and, from its applicability in situations where the miner's fuse could not be used, has been of much service in practice. Under-water blasting is now altogether carried on by this means. It is also useful because of the possibility of insuring the simultaneous action of many charges of powder placed at a distance from each other for the purpose of effecting the dislodgment of large masses of rock or earth, as was the case recently at Dover, where nine tons of gunpowder in three charges were simultaneously exploded in cavities cut at distances of seventy feet from the sea cliff, and detached with perfect safety 600,000 tons of rock.—All that is necessary in such a case is to enclose in each separate charge of powder such an apparatus as that shown in the cut, and connect them all with wires led up through the packing of the mine to a powerful galvanic battery with which they are to be put into connection at the moment when it is wished that the explosion should take place. In military operations it has been found, by experiments which

have been carried on by the Russian government through the instrumentality of Prof. Jacobi, that electric blasting may be exceedingly useful. It is believed to be the means in use in some of the "infernal machines" sunk off Cronstadt, and it has been recently used with success under the fortifications of Sebastopol.

It is found that large single pair voltaic arrangements are more powerful in producing heat, if no great length of wires is to be traversed, than numerous small plates formed with a battery. Accordingly, coiled plates of 400 square feet have been constructed, for the purpose of exhibiting on a great scale these effects. The names of Calorimotors or Deflagrators are given to them. If from one of the wires of such an apparatus, or even from that of a small battery, a thin leaf of metal be suspended, and a plate of copper in connection with the other wire

be brought into contact with its edge, (fig. 5,) brilliant combustion will ensue, and part of the metal will be dissipated in vapour. Gold leaf gives a whitish light; silver, a bright green; zinc, Dutch gold, and tin, displaying different characteristic colours.

Fig. 5

If these experiments be made with a powerful battery, and in darkness, they constitute some of the most imposing of electrical phenomena. A steel point in connection with one pole, and dragged across a file of the same metal in connection with the other, gives out copious showers of red sparks, similar to those emitted under the operations of the blacksmith.

By far the most splendid exhibition of the heating effect of the voltaic current consists in the light emitted from two charcoal points, brought so closely together when in connection with the wires of a powerful battery, as to allow of the passage of the current between them. It ought to be understood that this is not a light directly from the current itself, but rather that it proceeds from its conversion into heat in the charcoal, which thus becomes intensely luminous. Charcoal recently prepared from some dense wood, such as boxwood, answers well for this purpose, but is on the whole less effective than the dense coke got from the roofs of the retorts, in coal gas works.

This substance is either cut at once into pencils, or having been powdered, is pressed and hammered into moulds to give it density and form, and is then put into connection with the poles and steadied, the two points opposite each other by some arrangement, such as that represented in fig. 6,

Fig. 6

facility being afforded for regulating the distance between the points, so that the maximum light may be produced. That the light is not given

out by combustion of the charcoal, may be seen by immersing the whole in water, when the light will still be produced, though more feeble, or in a vacuum, by withdrawing the air from a glass globe surrounding the points, when the flame will become even more intense than in air. The greatest barrier hitherto experienced in the application of this most brilliant of all artificial lights, to the purposes of illumination, has consisted in the difficulty of regulating with sufficient nicety the distance of the charcoal points from each other, as the substance of one or both irregularly wastes away by the contact of the air, and by sublimation of the particles. This has been to some extent overcome by automatic arrangements of electro-magnets, as a substitute for the human hand, and to a considerable degree successfully. If to this we add the recently opened prospects, that the processes of many chemical manufactures may be made the means of affording abundant supplies of electricity, in a form to fit it for this purpose, we may exercise the hope that another brilliant achievement by science and art will be added to their many former contributions to human comfort and adornment.

On the subject of the heating effects of Electric currents, it will be only necessary to add, that they have been recently used in conjunction with the concentrated sun's rays, to effect the fusion of refractory minerals. The diamond has readily given way to this treatment, and melted into a globular bead, and according to some, plumbago and coke when thus treated, can be converted into the precious stone, not as beautiful as the real it may be, but giving close approximation to many of its characters.

We may next give a short exposition of the magnetic relations of the current, constituting what is called **ELECTRO-MAGNETISM**. The fundamental fact upon which this science is based, is the following:—If a magnetic needle free to move on its pivot, be brought into the neighbourhood of a wire carrying the voltaic current, the wire which, if it be a non-magnetic metal, such as copper, had previously no action on the magnet, now, by reason of the current, causes it to move, and in a way of which it is not at first easy to perceive the law. For example, if, as is represented in the cut, (fig. 7,) the current be

Fig. 7.

placed parallel to the needle and above it, the needle moves round on its axis to a new position, as shown by the dotted lines, and if the current be further approximated or be rendered more energetic, the needle will turn still more round till, if the force is powerful enough, a position of equilibrium is assumed at right angles to the

direction of the current, the directive force of the earth having been completely overcome. Farther round than this, no increase in the energy of the current can impel it. The only effect being, a greater pertinacity in retaining the new position in opposition to any force tending again to twist it towards parallelism with the current. If now we remove the current to a position below the needle instead of above, the poles will be

turned round in the opposite direction, as is represented in fig. 8. If the direction of the current in the wire be reversed while it remains in the same position, the motion

Fig. 8.

of the needle is instantly changed to the opposite direction, from which circumstances it follows, that, if the same current be carried in one direction, above the needle and back again, in the

opposite direction below it, as in fig. 9, the action of the two portions of the current will conspire to give the same new position of equilibrium, and that

Fig. 9.

the twisting effect will be doubled, and it is evident, that if the same current were again brought round, a fourfold effect might be produced, so that a weak current might be made by this principle of *multiplication* to produce almost any amount of action, and that this might be used as an index of the comparative strengths of different currents, which is accordingly taken advantage of, in the instrument called a galvanometer. If instead of placing the current above or below the needle, it be placed alongside of it, and in the same direction

as in fig. 10, it will be seen, that the same tendency to place itself across the direction of the current, will still be manifested by the one pole rising and the other being depressed; and if

Fig. 10.

the needle were only moveable in a vertical plane it would finish, if the current were strong enough, by placing itself vertically across the horizontal wire, but in the case of a magnet suspended on a point, this is not what occurs, for no sooner in the last mentioned arrange-

ment does the one pole rise above the current and the other pass below its level, than they immediately begin to move horizontally, and tend to twist the magnet spirally on the wire. By a careful inspection of the appearances, this can readily be noticed. After much difficulty, when these observations were first made, it became apparent that the influence, whatever it might be, tended to propel each pole of the magnet continually round the line of the current, but the two in opposite directions, (fig. 11.) It is clear, unless the needle were capable of being bent like a thread, the two poles could not continuously obey the forces tending respectively to

Fig. 11.

twist them in opposite directions round the wire, and that the only way in which they can manifest their *tendency* is, by taking up the cross

position which we have seen the needle to assume.

If one pole of the magnet could be liberated from the other, a continued circulation round the wire might be expected. This cannot be done, but the other may be rendered inactive by preventing the current from acting on it by leading it away from the needle after it has passed along only one of its ends. Were we to use a bent wire for this purpose, it is evident that the bent portion would interfere with the motion of the mag-

Fig. 12.

netic pole round the remainder of the wire. The difficulty, however, has been overcome by substituting a liquid conductor instead of a wire for the bent portion of the circuit. The magnet is bent as is represented in the cut so as to enable it to be supported in a vertical position on a pivot. It carries a small cup of mercury on its upper surface, into which the point of one of the battery wires dips, transmitting the current in a parallel direction near one of the halves of the magnet; it is then carried along a bent wire which dips into a circular channel of mercury, whence it passes by the small mercurial cup on the right away to the other wire of the battery, thus having only passed along one of the halves of the magnet, the other half having no current remains indifferent, and easily follows round in a continuous circuit after the other, as its opposite rotation is not called into action. Thus the remarkable spectacle is presented of a body con-

tinuously whirled round a fixed line by what appears to be a single force derived from that line in a direction always along the tangent to the circles described round it as a centre, (fig. 13.) We shall afterward see how this apparent physical anomaly has been reconciled with the ordinary laws of mechanics.

Fig. 13.

As may easily be supposed, from the universal laws of the equality of action and reaction, the wire is affected by an equal tendency to pass across the magnet, and this may be rendered evident by suspending a wire in the manner indicated in the woodcut where the ends dip

into mercurial cups A B, in metallic communication with other cups into which the wires of the battery are introduced, giving us a wire carrying a current and yet being free to turn itself on the pivot at B. If a magnetic bar be placed over B and parallel to the wire, it (the wire) will turn itself round to a direction at right angles, when it again stands stationary till the magnet is again moved or the current reversed, when a new rectangular position is assumed. By presenting a single magnetic pole to the wire in different positions it becomes evident from the directions of the attractions and repulsions that the real tendency is to rotate in a certain definite direction round the magnet, and that, if perfect freedom of motion were allowed, this result would be produced. Practically this is easy of actual accomplishment by means of even a current from a comparatively small battery, by an arrangement similar to that delineated in fig. 15. The current is made to descend from the cup

Fig. 14.

P, through the moveable wire w, which dips into the circular basin of mercury below, from which a wire carries it to the cup at Q, into which the wire from the opposite pole of the battery is made to dip. A magnet is bent to the form shown in the figure, and has one of its poles introduced through the bottom of the basin of mercury, while the other is placed at a distance, as at N, so as to remove its action on the wire. If the connections be complete and the current sufficiently powerful the wire performs continued

Fig. 15.

rotation. The current is made to descend from the cup P, through the moveable wire w, which dips into the circular basin of mercury below, from which a wire carries it to the cup at Q, into which the wire from the opposite pole of the battery is made to dip. A magnet is bent to the form shown in the figure, and has one of its poles introduced through the bottom of the basin of mercury, while the other is placed at a distance, as at N, so as to remove its action on the wire. If the connections be complete and the current sufficiently powerful the wire performs continued

revolutions round the pole *s*, in the same way as the magnetic pole itself did in the former experiments when the wire was fixed and the magnet free to move. Many curious varieties of these electro-magnetic rotatory apparatus have been at different times invented, one of the simplest of which is that where the battery itself is made to revolve by the influence transmitted from a magnetic pole placed in its interior, as represented, and round which it is free to turn. The figure represents a section of such an arrangement of about half the working size. The copper portion of the bottom pair is formed, on the principle of Hart's battery, to contain the acid, and to leave a free space in the interior, up which the magnet is passed, upon which the copper hangs by means of a pivot attached to an arch of wire, as shown at *c*. The zinc is also formed into a cylinder, and is suspended free to turn in the acid by means of a pivot resting on the wire of the copper and in clean metallic contact with it, so as to allow of the passage of the current. It is evident that the current in

Fig. 16.

passing from the copper to the zinc ascends in the first metal and descends in the other, so that opposite currents equal in quantity and energy are flowing parallel to the magnetic bar. So they ought to be impelled in contrary directions, which is really produced, and forms at once one of the most striking and at the same time most certain (so far as freedom from liability to failure is concerned) exhibitions of the actions of electro-magnetic rotatory forces. The Earth being a magnet, it might be conjectured from what has gone before, that a mutual influence must be exerted between the earth and a wire carrying a current, and that this is the case can be rendered manifest by means of the rectangularly bent and freely moveable wire used for examining the action of a common magnet, for no sooner is the current sent through that

Fig. 17.

rectangle than it turns itself as if a magnet had been presented to it, and arranges itself at rest perpendicular to the direction of the compass needle: and farther than this, Faraday has succeeded in devising an arrangement by which a wire can be caused when carrying an energetic electric

current to make a complete and continuous revolution by means of terrestrial magnetism alone. A slender copper wire is fixed to a hook and rendered buoyant by a small cork ball at the lower end, which dips into a basin of mercury placed in connection with the opposite pole of the battery. When the current is sufficiently powerful the wire performs a conical revolution round the lines of magnetic force, which are in our latitude inclined at an angle of 70° . At the equator, where the lines of force are horizontal, this experiment could not in this way be made. This arrangement is shown in fig. 17.

The inductive effects of the electric current may be next noticed. These are of two kinds—1st, the induction of other electric currents in conducting bodies, that is, bodies capable of conducting electricity, in their neighbourhood; and 2d, the induction of magnetism in iron and other bodies capable of taking on magnetic polarity. The second, viz., the induction of magnetism in iron, is treated of in the article *ELECTRO-MAGNET*, and need not be here further alluded to. The induction of electric currents in neighbouring conductors is well illustrated in an experiment of the following kind. Let two coils of insulated copper wire (that is copper wire covered with silk or cotton thread to prevent metallic contact with other portions which may touch any particular part) be taken, and one connected with a galvanometer, while the other has one of its ends, as at *x* in the figure, connected with one of the poles of a battery; and is placed parallel to and near the first coil, but not in metallic contact with it. The galvanometer being properly arranged, as in fig. 18, so that the needle when at rest stands

Fig. 18.

parallel to the wires which surround it, let the other end, *p*, of the coil be connected with the remaining pole of the battery, it will be seen that on the instant of completing the circuit in the first coil, the needles of the galvanometer are moved, indicating a current in the second coil, though no such current can have come directly from the battery, as no metallic or conducting channel exists between them. It will also be noticed that after oscillating for a while the galvanometer needles will return to their first position, indicating the cessation of the current in its wire. Let now the connection with the battery be broken, and it will be found that the needles are again moved by a sudden current in their wire, which, however, like the first, ceases immediately.

If the connection be again made with the battery another momentary current is indicated by the galvanometer and so on, and it is also noticed that the current which occurs for a moment in the second when the primary current is established in the first coil, is in a direction contrary to the course of the current in that coil, and that the one produced on breaking the circuit is in the same direction as the primary current. These are called momentary, secondary, or inductive currents. That they are of high intensity, nay, of far higher intensity than the primary current from the battery, can be easily perceived by the influence on the senses on applying the ends of the wires of the two coils respectively to the tongue or to the moist hands merely if the coils be long. Again, if the two coils be brought near to each other and the current let on to the primary, as has been said, the induced current in the secondary wire will only continue for a moment, and after a few oscillations the needle will return again to its zero point. While this is the case, let the secondary coil be rapidly moved away from the primary, which is still carrying the battery current, and instantly the needles will move indicating that the motion of the wire in the neighbourhood of the current has served to excite a current in the secondary, which ceases on the coil being allowed to rest for a little and is again roused up by even the slightest movement. It is more energetic the more active the movements, especially of approach and recession, are of the two coils from each other, a contrary current being produced by approach to that developed by recession.—If a third coil be added in the neighbourhood of the second, connected also with another galvanometer, we should expect to have two currents in the tertiary every time that the current in the primary is made or broken; for, as the making of the current in the primary gives rise to a momentary current in the secondary, which, short in duration though it be, must have both a beginning and an end; each of these we might expect would excite a current in the tertiary wire, which two currents ought to be in contrary direction and the one closely following the other; or perhaps they might neutralize each other's effects, and no current might take place. Neither of these, however, occurs, for only one current is observed in the tertiary wire at the time of making or breaking the current in the primary, and the current is sufficiently strong to show that neutralization by means of equal and opposite currents at the same instant by no means occurs in the tertiary wire. To account for this, it has been conjectured by recent experimenters that for some reason the current in one direction is much stronger than that in the contrary direction, and it is the effect of it alone that is observed.—Recently, series of five or six coils have been experimented on, so as to discover the kind of inductive currents they give rise to in each other, when mutually excited, and the influence

of the primary current transmitted along from one to the other. Those who are interested in such researches, will find in the published papers of Dove, Weber, and Abria, the information they desire. It ought to be understood that the form of a coil is in no way necessary to the development of electrical currents in one conductor, at the moment when another conductor in the neighbourhood has a current sent through it. All that is necessary, is only that the two conductors should be in each other's vicinity, and if they be wires, that they be not perpendicular the one to the other. The action of many turns of a coil only multiplies the effect which would result from the length of wire of one turn. As to the cause of these secondary currents, the most probable supposition that has been made is, that they result from the induction arising from the wave of electric tension which rushes along the wire, when the battery connection is first established, acting on the neutral electricity of this conductor, repelling one portion and attracting the opposite kind, and thus disturbing the electric repose, and causing a momentary rush in opposite directions of the two electricities, just as occurs in a body excited by the inductive action of another excited by frictional electricity, where a current of electricity occurs between different parts of the body till the new state of equilibrium is attained, when repose again ensues, until the inductive body is withdrawn, giving rise to the currents due to the return of matters to their original state. It will easily be supposed that the currents induced in one conductor by the presence of another carrying a current will be greater, as the two conductors are more closely approximated. Accordingly, one of the best as well as most convenient modes of arrangement for procuring these induced currents, is to coil the first wire on a reel or bobbin in two or three layers, and then over these wrap on the secondary coil, as is represented in the annexed cut. As has been said, the

secondary currents are much more energetic, though very short in duration, than the primary current from the battery, and for some purposes, where continuity of action is not required, and only great intensity is chiefly desirable, as for many medical purposes, they are useful and efficient, and exceedingly easily procured, compared with the costly and ponderous batteries which would be requisite to produce similar currents by the more ordinary voltaic arrangements. To construct a coil capable of giving currents powerful enough for medical purposes, all that is required is, to wind on a wooden bobbin with a hollow axis about one inch in diameter, about thirty yards of common bell copper wire, covered with cotton or silk thread, leaving its terminations

Fig. 12.

free to be connected with the battery. Above this, let about four hundred yards of fine copper wire about $\frac{1}{10}$ of an inch in diameter, also insulated, be wound on in successive coils, leaving the ends free, and attaching to them pieces of tin, or brass tube, to act as conductors. If now a small battery, or even a single voltaic pair of four or five inches square, be connected with the ends of the thick wire, and the human hands moistened with water, be placed on the conducting tubes of the small wire, a shock will be felt each time that the connection with the battery is made or broken. It will also be found that a piece of soft iron introduced into the interior of the coils, will greatly increase the intensity of the shock, and still more will this be the case, if a faggot of iron wires be used for this purpose. In order to make and break the connection with the battery, so as to give a rapidly intermitting current in the primary wire, a simple automatic apparatus is represented in the figure. *s* is a plate of soft

Fig. 20.

iron attached to a piece of watch spring, fastened at the opposite end to a stud rising from the bobbin, and having one pole of the battery in connection with it. On the lower surface of the

watch spring is soldered a small slip of platinum, which when *s* is not dragged down on the faggot of wires by their attraction, rests against a platinum wire at *o*, in connection with one end of the primary coil. The other end of the primary coil is put in communication with the remaining pole of the battery, so that when the poles of the battery are attached to *N* and *P*, the current passes round the primary coil, and magnetizes the iron wires, which instantly drag down *s*, separate the platinum surfaces, thus interrupting the primary current and causing a direct current in the secondary wire, the reverse current having been induced when the connection was completed. The plate *s* being no longer attracted, is lifted by the spring into contact with the platinum point, and again establishes the current, causing the inverse secondary induction, and also magnetizing the faggot of wires, which instantly again draws down *s* and interrupts the connection, giving a rapid succession of momentary currents. The platinum surfaces are necessary, in order to maintain unoxidated points of contact. It has been found, that tubes of different non-magnetic metals introduced into the interior of the bobbin, altogether intercept the effect produced by the iron placed in their interior, and after considerable difficulty, this curious effect

has been traced to the development of circular currents in the substance of the tube, by the inductive action which is the subject of which we are now treating, and that these currents react injuriously on the secondary wire, as they are in the opposite direction to the primary current in the coil, and tend to neutralize its effects on the secondary wire. That this is the true cause, is proved by dividing the tube by a longitudinal slit from end to end, which totally prevents its screening action. The superficial currents caused in the same way on a rod of iron introduced into the coil, also act injuriously, and accordingly it has been found better to employ wires, and still better to use them covered with thread to prevent mutual communication. As to the explanation of this increase of the secondary currents, by the introduction of iron into the coils, while other metals have no such effects, the reader is referred to a further stage of this article, when the object of magneto-electricity is treated of. This circumstance of the induction of a secondary current of electricity in neighbouring bodies, explains the fact so often observed, that, though by simply joining the wires of a small galvanic pair, no spark is produced, yet, if a coil of wire be made part of the current, a vivid spark appears on making and breaking the connections. It may be supposed that this was owing to the wire acting as a reservoir, but the observation, that the same increase of effect does not take place if the wire is merely extended, and that the form of a closely folded coil is necessary, points to the true action which gives rise to the momentary movement of a large quantity of electricity, as the reaction by induction of one layer of the coil over another, according to the principles just laid down. A piece of iron introduced into the coil of wire also in this case, increases the intensity of the light. It will be remembered, that the secondary currents is in the reverse direction to the original current when the current is made, and in the same direction as the current when the connection is broken, so that in the case of the action of one part of the primary wire acting on another part, we would expect that the induced current would tend to oppose the primary on making the connection, and would assist or enforce it, by moving in the same direction when contact with the battery is broken, and this is found to be the case, for it is with the latter operation that the most vivid spark is seen. It is observed in the construction of coil machines for medical purposes, that the character of the shock is influenced by the thickness of the wire used as the secondary coil. M. Ruhmkorff of Paris, by using a condenser composed of oil-silk coated on each side with tin foil, has constructed induction coils of very great power.

One of the most remarkable discoveries of modern times, is that due to Faraday, of what is called *magneto-electric induction*. It can be most easily observed, by connecting the two

ELE

ends of a coil of insulated copper wire with a galvanometer, placed at a distance of a yard or two, and introducing suddenly into the interior of the coil the end of a magnetic bar; a current will instantly be indicated in the wire, which, however, will immediately cease if the magnet be allowed to rest in the coil, the galvanometer needle returning to zero. If then the magnet be

Fig. 21.

withdrawn from the coil, another momentary current in a reverse direction will be exhibited by the galvanometer. The intensity of these induced currents varies as the strength of the magnets, the length of the coil, and the rapidity with which the magnet is moved. It is easy to get currents intense enough to be felt as a severe shock through the human body. These currents, which are the effect of the reaction of the magnet on the wire, (as magnetism is produced by an electric current, so here a magnet produces electricity,) are most easily explained on the theory of Ampere, that a magnet consists of an arrangement of electric currents, making this case only a variety of the last considered, viz.:—the induction of one electric current by the sudden presence or removal of another in the neighbourhood of a conductor. Instead of producing magnetism in the interior of the coil of wire, by introducing suddenly a magnet, the same thing might be produced by temporarily magnetizing a bar of soft iron round which the coil had been wound, by bringing in contact with its end the pole of a magnet, and then withdrawing it. If the steel magnet be of the form of a horse-shoe, then the iron bar may be bent into a similar form, and have the wire wound in two coils for facility of arrangement, as represented in the annexed figure. If instead

Fig. 22.

of removing the magnet, it be suddenly twisted half round on its axis *A B*, the induced magnetism in the iron will cease, and a current be produced in the coil. If the revolution be further continued till the plane of the two metals coincide, the polarity of the iron will be again produced, but in an opposite direction, giving rise to a contrary current and so on. In order that these currents be produced, it is necessary that the ends of the coil of wire should

ELE

be joined by some good conductor, or form what is called a closed circuit. This is done by the galvanometer wire, in the case of experiments made with it to detect the currents. If, however, we wish to see the spark which they are capable of producing, the complete metallic circuit of the wire must be broken, and it is of importance that this should be done at the moment when the iron is being magnetized or unmagnetized, as it is then that the current exists. Many arrangements have been devised for rapidly whirling the iron with its coils in front of the magnet, and for breaking the continuity of the wire of the coil, at the proper parts of the revolution, that is when the iron within the coil is being magnetized, or unmagnetized. Fig. 23, represents one of the most

Fig. 23.

useful of these magneto-electric machines, as they are called. *M* is a powerful magnetic battery, consisting of three or four strong horse-shoe magnets, fastened to the upright board *X*, by a clamp which allows of adjustment that they may be brought more or less forward so as to be applied closely, but without contact, to the ends of the short soft iron bars enclosed in the coils *A* and *B*. These coils consist of copper wire covered with silk thread, and wound on the soft iron cores, which again are united so as to form a kind of horse-shoe, by means of the iron bar seen stretching from *A* to *B*. Through this bar there passes the axle which carries the coils and breaks, and is driven by the multiplying wheel at a high velocity. Near the point of the axle is fixed the break *P*, which is composed generally of brass, and has one of the ends of the coil in connection with it, while at the same time it is pressed on by the bent wire from the metallic pillar *L*. The pillar *L* is in connection with the metal of the support *N*,

from which the wire *x* rises, and rests against the ring *z*. This ring is separated from the axis by an insulating piece of ivory or dry wood, and has the other end of the coil soldered to it, so that one end of the coil being in communication with the axis, carrying the break and the other end with this ring *z*, the current will be complete through the wire *x* and *r* and *w*, between the two ends of the coil, when the wire *w* is in contact with the break. From what has preceded, it will be understood that, during one complete revolution of the axis, the cores of the coils being twice magnetized and twice demagnetized, there will be four momentary currents excited in the coils, and that two of these will be in one direction, and two in the opposite. The spark is most clearly seen, if the break be so arranged, that the current is broken when the line joining the centre of the two coils is vertical. For chemical decomposition, it would be important, that only currents in one direction should be employed. This will be accomplished by allowing the current to be closed during one-half the revolution, thus confining the current to the coils themselves, and not permitting them to pass to the point of operation; but the question arises, during which half of the revolution the same direction of the current will be maintained. Now it is evident that as demagnetizing and magnetizing by an opposite pole, both give a reverse current, they will agree in direction among themselves, so that as either coil passes from one pole of the magnet towards the other, the currents may be used by breaking the connection, and allowing them to pass to effect chemical action; but that the current must be closed while the coil passes again from that pole and towards the next, the current being then completed in the wire, through the break. It is found, that coils formed of thick wire, give bright sparks and currents capable of producing heat and magnetism, while very great lengths of exceedingly thin wire produce much greater chemical power and far more energetic shocks when the human hands are applied to conductors in communication with the ends of the coil. The first are called quantity, and the second intensity armatures. For the purpose of communicating the shock or applying these currents medically, the brass conductors *s* and *r*, are used and applied, as in the case of the galvanic current from an ordinary battery, while the coils are driven round. The wires attached to these conductors pass the one to pillar *v*, while the other has its end pushed into a hole in the end of the axis. The strength of the current increases as the rapidity of revolution increases, agreeing with what was said, as to the cause of these currents being the induction produced by the sudden presence of the magnetic pole, or according to Ampere, the electric currents in that pole. This magneto-electric machine is exceedingly useful in the medical application of the electric current. It can be regulated in in-

tensity with the greatest nicety, by applying a piece of iron across, between the limbs of the magnet, and sliding it more or less near the poles. It is always ready, night or day, and does not need the same amount of preparation as a battery, or even the ordinary coil machine, where, at least, a single voltaic pair is required. It has been most useful as a means of resuscitation in drowning, in threatened death from chloroform, and in many other similar cases. It has been proposed as a means of corporal punishment in the army, communicating pain without mutilation. It has been, and is still, used on a large scale in electro-metallurgy. It is in constant use as a substitute for batteries in the Magnetic Telegraph, and may be regarded as one of the most remarkable of human inventions.

As important both for their theoretical and practical bearings, it may be proper here to refer to the phenomena depending on magneto-electric induction, brought to light by the researches of Arago, Babbage, and Herschel. If a disc of any metal be placed over a freely moveable magnet, as in fig. 24, and set into circular motion, the needle will gradually begin to follow the motion of the disc, and if the rapidity be sufficiently increased and the plate be placed near enough, will ultimately revolve with greater and greater rapidity. That this effect is not due to the currents of air Arago proved by interposing a plate of paper or glass, and he conjectured that rotation was a source of magnetism or, at least, of electrical currents.

Fig. 24.

Herschel and Babbage showed that if a number of slits or cuts in a radial direction are made in the disc of metal, the revolving motion is greatly enfeebled, and that different metals revolve with energy proportional to their conducting power. Faraday ultimately succeeded in proving that these phenomena were wholly due to the currents induced in a moving conductor by the presence of a magnet, in the way explained in the preceding paragraphs. As may be at once inferred from such experiments, caution must be exercised in drawing conclusions as to the direct magnetic or non-magnetic properties of bodies from their movements in the neighbourhood of magnets. The mode of oscillations must be used with suspicion only. There can be no doubt that metallic pendulums must be affected in the rapidity of their oscillations to some extent by the influences of terrestrial magnetism in the way here referred to. A copper ball suspended between the poles of a powerful electro-magnet can be easily made to turn itself rapidly round by magnetizing and unmagnetizing the iron, and it ought to be recollected that these motions may in many cases mask or modify the appearances presented in researches on the properties of the

magnetic field and on diamagnetism.—As a practical example of the manner in which Arago's discovery has been turned to account, the mode of reducing the oscillations and thus steadying the needles of the mariner's compass may be referred to. A ring of copper or other good conducting non-magnetic metal is placed round the compass box and as close to the needle as practicable consistent with free motion. The effect of this is that the oscillations are greatly reduced and the uncertainty in steering on an agitated sea considerably diminished. The theory of this action can be at once understood from what has already been mentioned: the needle tends to drag round the copper ring after it in its excursions, and as action and reaction are equal and opposite, the needle itself is acted on by a corresponding force dragging it back, so that rest, after any disturbance is much more rapidly produced than if no such action existed. Copper is used as the ring on account of its high conducting qualities, at the same time that it can be got pure and free from mixture with iron or other magnetic material which would act injuriously on the compass needle by producing contending polarities in its neighbourhood and interfere with the directive force of the earth in the manner known as local attraction.

We shall now give some account of the different suppositions that have been made as to the nature of the mutual influence which is exerted between an electric current and a magnet. Any general theory must account for such phenomena as the attraction of iron filings by a wire carrying a current, the magnetic properties of coiled currents, the directive power of a current on a magnet or a magnet on a current, and the continued rotation of a magnetic pole round a current and *vice versa*. The most obvious and the earliest supposition was, that, by the conflict of the two electricities within the wire, magnetic properties were acquired with the polar directions at right angles to the current, so that a section of the wire carrying a current might be assimilated to a series of small magnets laid round in a circle as in the annexed figure. A magnetic needle in

Fig. 25.

the neighbourhood of this series would, from the known laws of magnetic action, be caused to place itself parallel and with opposite polar arrangement to the nearest magnet. To this it may be objected that the whole would be analogous to a closed magnetic circle or to a magnetized ring which would have no action on external magnets, and besides this objection no explanation is afforded by this hypothesis of the rotation of a magnetic pole round the wire. To remedy this Wollaston and others adopted the supposition that by the passage of the electricities in the wire, the two magnetic fluids that accompanied them were put into a spiral or vortigenous motion in

opposite directions, and that they thus tended to draw along with them the magnetic poles. Thus the real force exerted on the magnet by the wire was in a circular direction round the course of the current or always in the direction of a tangent to the circle described round the wire, hence it was called a tangential force. The magnetic pole was thus driven round in the same way as a ball would be impelled by a revolving wheel if it were placed between its spokes. To account for these attractions and repulsions exerted between two currents it was supposed that magnetic fluids of the same name attracted each other if they moved in opposite directions, but repelled if they moved in the same direction, and thus by a highly artificial and cumbrous series of gratuitous suppositions most of the phenomena of electro-magnetism could be accounted for. It may be remarked, however, that there is no other instance among physical forces of the existence of a tangential force as the primitive influence exerted between two bodies, there being in all other cases an attraction or repulsion only along the straight line which joins the acting points. It is to the illustrious Frenchman, Ampere, that science is indebted for a theory at once simple and comprehensive, which, while it has served to render all the phenomena of electro-magnetism subject to rigid calculation, and is therefore in this respect far preferable to any of the others, yet demands no hypothesis so repugnant to the previously ascertained mechanical principles as those necessarily implied in the others. Ampere's theory, which has gained for its author the title of the Newton of electricity, now plays so important a part in physical science that it cannot here be passed over without an attempt to expound its nature and some of its consequences. Ampere discovered by experiment that electric currents attract and repel each other, and he makes this the foundation of his theory, assuming that round the constituent molecules of magnets there are perpetually circulating electric currents, and that the attractions and repulsions exerted between magnets and electric currents are due alone to the mutual actions between the currents, thus setting aside, *in toto*, the ordinary hypotheses of magnetic fluids and all tangential and transverse magnetic forces. He thus, successfully, by calculation and experiment, referred the whole class of electro-magnetic rotations, magnetic properties of coils, the inductive actions of magnets on neighbouring conductors, and even the magnetic properties of the earth itself, to one sole hypothesis and a fact well ascertained by experiment: the hypothesis being that a magnet consists of a series of perpetually circulating electric currents, and the fact, that electric currents attract or repel each other. The first point necessary for the establishment of this theory was to ascertain the laws of the force by which one electric current acts on another; or, in other words, to ascertain the form and the value of the constants in the expressions which

represent the force with which under all circumstances of length, distance, intensity, shape, and position, any one current acts on another. In order to this it can readily be ascertained by means of a wire carrying a current and rendered moveable in any manner, as, for instance, in the way shown in the figure, that if another current be brought parallel to it they will repel each other

Fig. 26.

if they be moving in the same direction, but attract if they move in the opposite directions; and, moreover, that the attraction and repulsion is less as the angle contained between the positions of the wires increases till when they are at right angles it ceases, as is evident from the fact that it must change from attraction to repulsion or vice versa, so that in this position the function which represents the mutual action must be zero. It may also be assumed that the action of each current is proportional to its intensity, and consequently when these two act on each other the mutual influence will be proportional to the product of these intensities. It is evident that the force will vary with the distance between the acting points of the currents, and therefore it will be impossible to obtain a general expression for this mutual influence for any but small portions of currents, so small that their length may be regarded as evanescent compared with their mutual distance. It is impossible to experiment with parts of currents answering these conditions and at the same time excluding the action of the remainder of the currents; but it may be assumed that the action of *elements* or currents so small that the distance of all their parts may be reckoned constant and designated by d , varies inversely as d^2 . This is more particularly probable since, if it be the case, we know from the investigations of Laplace and Biot that if each element of an indefinite rectilineal current act on a point in its neighbourhood with a force varying inversely as the square of the distance, then the whole line will act with a force varying inversely as the simple distance merely, and experiments with currents can be made in circumstances similar to this, and the results confirm the supposition. Also, the same law of force is easily deduced from the fact demonstrated by experiment that the intensities being equal, if the length and number of the currents be proportional to the distance, the effect of any series will be the same on an element, or small portion of a current: for instance, in fig. 27, c will be as much affected by the single short current at P , as by the two doubly long currents at R , or the four currents each four times as long at s , a distance four times as great as the single current

at P , the unity of distance, and it is easy to show that according to no other law than the inverse square would this follow.

For, representing by n the undetermined power of the distance according to which the force in each element acts, then we should have the force at any distance, d represented by an expression proportional to d^n , because the length of each current increases as d , and the number of currents also increase as d , so, for these two reasons we should have d^2 as the law of the variation of the

Fig. 27.

inherent strength of the force in such an arrangement as that in the figure, but, by supposition, its action on m is to be proportional to $\frac{1}{d^n}$ so its total action will be represented by $\frac{d^2}{d^n}$

and this at the unity of distance becomes merely unity. But by experiment, this is the same at all distances, so we have $\frac{d^2}{d^n} = 1$ or d^2

$= d^n$ or $n = 2$, proving that the inverse square is the true law, according to which the action of the force varies with the distance in the case of elementary portions of currents acting on each other. This reasoning may appear to be vitiated by being founded on the case of currents of finite length, but the reader will easily perceive that this is not the fact, as integration would give the same result. In attempting to construct an expression which shall embody what has preceded into a general formula for calculation, difficulty was experienced, from the circumstance that the influence which extends between the elements of two electrical currents, varies not only with their distance and mutual position, but also with the relative directions of the electrical currents with reference to the line joining their centres. The simplest case of this kind is where the currents are parallel to each other, and perpendicular to the line joining their centres, as in fig. 28, in which case they attract or

Fig. 28.

repel each other with the maximum force. In the case, however, that either or both the currents should be oblique to the line joining their centres, as seen in the position of B' in fig. 29, we know that the maximum force of A' is exerted on B' along the line joining their centres, but experiment proves that the maximum force of B' is

Fig. 29.

not exerted along this line, but along a line perpendicular to itself, as along sP , and we wish to know how much of that force is really

exerted along oblique lines joining the centres of the two elements. To this Ampere was assisted by the results of experiments which prove that a twisted or sinuous current, of any form, exercises the same action on another current, as a straight current terminated at the

Fig. 30.

same points would do. In the figure, the effect of the current passing along the straight and twisted wire would be null, and thus it was easy to see that the inclined elements might be replaced by two component currents, one in the direction of the line joining the centres of the two elements, and which, experiment proves, has no effect on that element, and another perpendicular to it, which has the full effect due to its shortened length. Thus, the single straight current CB'' , fig. 31, is replaced by the two currents CD and DB'' , which, experiment

proves, would produce exactly the same effect, while it, at the same time, proves that DB'' alone would exercise no effect on a current in the direction of its own length, or, at least, none of which we need at present take account, and so it may be neglected, and the full effect deduced from CD . But, as the effects of CD and CB'' will be to each other as their lengths, and these are as the lines CD and CB'' ; and $CD = CB'' \sin. \angle B''CD$, that is, the force in the direction of the line joining the centres is equal to the whole force of the element multiplied by the sine of the angle which its direction makes with that line. The same result must follow if the other elements be also oblique to this line.—If e denote the length of the one element, and i its intensity, e' and i' representing the same for the other element, while d represents the distance of their centres and θ, θ' the angles which these directions respectively make with the line joining their centres, then, because the mutual action of two forces is equal to the product of each separate action, we should have, by what has preceded

$$f = \frac{e i \sin. \theta e' i' \sin. \theta'}{d^2}$$

or

$$f = \frac{e e' i i' \sin. \theta \sin. \theta'}{d^2}$$

But this, be it observed, only applies to the case of the two elements of currents being in the same plane, and in order to render it applicable to every position, we must decompose one of the forces into two components, one of them parallel to the plane of the other element, and another perpendicular to that plane, which last, as it exercises in general little effect, may till afterwards be neglected. The first component, viz.

that parallel to the plane of the other element, may be got in the way which may be understood from fig. 33, where $PQRS$ represents a plane passing through one of the elements and through the line which joins the centres of the two, and $TUVW$ is a plane passing through the other element and the line which joins them; then AL exhibits the one element, and BC the one in the other plane. If CD be projected on the plane $PQRS$, BD may represent this projection, and if ϕ denote the angle contained between these two planes, then $BC \cos. \phi$ will be its component in the other plane, which would then, were it not perpendicular to the line joining the centre, be affected by the sine of the angle which it makes with it as has already been indicated; so we arrive at the general form for all possible positions of the two elements whether in the same plane or not

Fig. 33.

$$f = \frac{i i' e e' \sin. \theta \sin. \theta' \cos. \phi}{d^2}$$

It is evident by inspection of this expression, that the force vanishes where θ or θ' disappear, that is, when either of the elements becomes parallel to the line joining their centres, and this, whatever may be the direction of the other element. Now, experiment proves that this is not the fact except in the single case when the other element is at right angles to the line joining the centres, or in other words, when the two elements are at right angles, and at the same time the length of one of the elements is directly pointed at the centre of the other. It is easily proved by experiment that the parts of two currents, or two parts of the same current repel each other if they are in the same straight line: as, for instance, in fig. 34, where the two elements are in the position A and B'' . Also, it appears that this repulsion does not in any degree exist, or at least, that it is at its minimum when the two elements are parallel, as at A and B . No indication of this is found in the expression for the force, which must, therefore, be imperfect. An additional term will remedy this if it be so constructed that it shall vanish when either of the two currents are perpendicular to the line joining their centres, and that it shall be a maximum when they both coincide with that line. Now, the cosines of the angles θ and θ' , have these qualities, and it is probable that this term ought to be some function of these

Fig. 34.

cosines. For the purpose of ascertaining the true form and constants of this term, Ampere adopted the product of those cosines affected with an undetermined coefficient, which we may denote by m , and afterwards calculated, by integrating the expression, the rotatory action exerted by a closed current on an element of another circular conductor, and, as experiment proves that action to be null, he equated this result to zero, and thus gets

$$2 + 2m - 1 = 0$$

or

$$m = -\frac{1}{2}.$$

By substituting this value for m , we get as the complete expression of the attraction between two elements of electric currents in any direction, and of any intensity—

$$f = \frac{i i' e e'}{d^2} (\sin. \theta, \sin. \theta', \cos. \phi - \frac{1}{2} \cos. \theta, \cos. \theta').$$

When calculation is to be made of the attraction of finite lengths of current, integration must be resorted to, in which case, if l and l' be the lengths of currents, $d l$ and $d l'$ would be substituted for e and e' .—A multitude of results have been deduced from this expression by Ampere, Savary, and more recently by Plana. We can but briefly point out some of its consequences. It must be observed, that in order that the expression may include the property of electric currents attracting each other when in the same direction, and repelling when in opposite, it is necessary to adopt a corresponding convention with reference to the angles θ and θ' , in order that in the proper circumstances these sines may be negative or positive, so as that the expression may indicate attraction when positive, or repulsion when negative. This will be accomplished if the angle θ be always measured between the part of the current produced in its own direction and the part of the straight line joining the centres of the two elements produced; thus, with regard to the two elements $B E$ and $A K$, fig. 35,

Fig. 35.

going in the direction of the arrows we take as the angles θ and θ' , $\angle B D F$ and $\angle A C P$; then those on the upper and right side of the joining line will be reckoned positive, and those on the left and lower side negative. One of the most interesting results of Ampere's investigation was the explanation they afforded of the rotation of a wire round a magnet, or of a magnet round a wire. This at once follows from the general expression, if we admit that a magnet is composed of circular currents circulating round the molecules, and arranged in planes perpendicular to the magnetic axis, as may be represented in section in fig. 36. It can be shown that, as the contiguous portions of the elementary molecular currents being in

opposite directions, will oppose each other, and produce a null effect, the whole system will be merely equivalent to an external current circulating in the plane of the section, and in the same direction as the molecular currents; so a magnet, in this theory, is represented by a contiguous series of closed currents arranged perpendicular to its axis, and of the same diameter as the magnet itself. Such an arrangement Ampere designates as a solenoid, and shows by calculation that it may in all cases take the place of a magnet. In this way, we, in attempting to account for the rotation of a wire round a magnet, substitute for the magnetic pole a circular current of the same diameter. Let us represent a small portion of this current by the straight line $A B$, fig. 37, and an element of the current which is to be made to rotate round it by L , then we find, by the formula, with regard to any element of the current to the right of L , as for instance, B , that its action on L is repulsive, for, θ , the angle at L , is negative, and the angle θ' , at B , is positive, hence $\sin. \theta$ is negative, and $\sin. \theta'$ positive, and when substituted in the formula they give a negative attraction or a repulsion, by which the element L would be impelled in a direction from right to left by B . It is clear that the same result must follow for all the elements of the current to the right of L . But any element, as A on the left of L , will give attraction; the angle θ , at L , being negative, its sine is negative; and the angle θ' , at A , being also negative, these two negatives being multiplied together, would give a positive result when substituted in the expression for f , which is therefore positive. As in each case the angle ϕ , may be neglected, so in this one, L would be drawn towards A , which attraction would therefore conspire with the repulsion from B , and give a tendency to move in a direction against the current in A and B . As this would be the result for every element of these currents when integration was applied, the whole actions would conspire to produce a continued rotation round the magnetic pole, and thus we get altogether rid of the improbable supposition of a tangential force, by the substitution of a mere attraction or repulsion. A little consideration will show that if the current were fixed, and the magnet moveable, the same attraction and repulsion, action and reaction being equal, would cause the magnet to turn on its axis, or, if

Fig. 36.

Fig. 37.

they afforded of the rotation of a wire round a magnet, or of a magnet round a wire. This at once follows from the general expression, if we admit that a magnet is composed of circular currents circulating round the molecules, and arranged in planes perpendicular to the magnetic axis, as may be represented in section in fig. 36. It can be shown that, as the contiguous portions of the elementary molecular currents being in

proper arrangements were made, to revolve round the wire. Exact calculation by means of the general expression for the action of magnets on each other, on the supposition that they are solenoids, has led to results which are in perfect conformity with the known magnetic laws. For instance, Ampere has proved that the total action of two solenoids upon each other may be represented by a force emanating from each end of the one towards each end of the other, viz. an attraction and repulsion, as is shown in fig. 38

Fig. 38.

—the attractions, by the continuous, and the repulsions by the interrupted lines, and that each of these forces acts according to the inverse square of the distance. This is exactly the case of magnetic bars, so the magnets act at least as if they were solenoids.—

According to Ampere's view, terrestrial magnetism is nothing more than the effect of electric currents circulating continually from east to west round the earth, which is by no means impossible. Faraday's discovery of the induction of electric currents by magnets moving in the neighbourhood of other bodies, is thus also simplified, and referred to the induction of electricity by the electric currents in the magnet. Recently, different attempts have been made to modify the hypothesis of Ampere, in so far as the nature and modes of circulation of the electric currents round the elementary molecules is concerned. Weber, De la Rive, and others, have been engaged in such speculations in connection with the subject of diamagnetism, and Tyndal's researches have thrown doubts not only on this but on all existing theories of magnetism.

Electrolysis = *Electro-chemical decomposition*: a term of Faraday's.

Electrolyte. A body that is directly decomposed by the electric current, such as *water*—is named by Mr. Faraday, an electrolyte.

Electro-Magnet. A current of electricity itself possesses magnetic properties, as evinced by the attraction of iron filings toward the conducting wire of a voltaic battery. If the wire be coiled up into a flat spiral, and suspended so as to allow of its freely turning on a vertical axis while it carries the current, it will arrange itself like a magnetic needle, and exhibit the two opposite magnetic polarities on its two faces,

Fig. 1.

being attracted or repelled by the ordinary magnetic poles, and may therefore be called a true electro-magnet. If the conducting wire be coiled into a long spiral or cylindrical form, as in fig. 1, a still closer approximation to the characters of a magnetic bar will be produced with the opposite poles at the two ends, the in-

tensity of the magnetic power becoming greater as the strength of the voltaic current increases, and also as the number of coils is augmented. Such coils or helices turn themselves, when free to move, into the direction of the magnetic meridian; and a small floating battery of a single pair of copper and zinc plates placed in a glass tube containing diluted acid, and supported by a cork float with a coil of wire soldered to the plates, as in fig. 2, may be substituted when set

Fig. 2.

to float in a vessel of water, for the magnetic needle, answering all the purposes of a compass without any of the ordinary magnetism, and might therefore be called an electro-magnetic compass. If into the interior of a coil of wire carrying a current there be introduced a bar of hardened steel, it will instantly be converted into a magnet, and if the current be intense enough, it will be magnetized to saturation, and thus excellent permanent magnets can be most expeditiously made; but it is upon soft iron that the magnetizing powers of the voltaic current are most powerfully exercised. Thus, if a copper wire be coiled round a piece of soft iron, and a current sent through it, the iron will instantly acquire exceedingly energetic magnetic properties, and indeed this is the mode in which by far the most powerful magnets can be constructed. A bar of well annealed soft iron, 6 inches long by 1 inch in diameter, having about 30 or 40 feet of copper bell-wire covered by silk or cotton thread, wound round it in close coils from end to end, becomes, when carrying the current from a battery of three or four pairs of 4-inch-square plates, an exceedingly powerful magnet capable of magnetizing compass needles to saturation, and exhibiting in a striking way most of the effects of magnetism. When very great power is required, the form of a horse-shoe, or of the letter U, is generally given to the iron bar. Care must be given to the selection of the best and softest iron. The copper wire should be thickish, say about No. 12, and should not be strained or twisted, lest its conducting powers be injured. It is generally wound on in several lengths, the separate ends being soldered to two different thick wires, for connection with the battery, taking care to wind on all the coils in

Fig. 3.

It is generally wound on in several lengths, the separate ends being soldered to two different thick wires, for connection with the battery, taking care to wind on all the coils in

the same direction, and to solder the beginnings of all of them to one wire, while the ends are soldered to another, as in fig. 3. The electro-magnet belonging to the Faculty of Sciences of Paris is capable of lifting a weight of three tons when an energetic current is sent through its 20,000 feet of copper wire. Electro-magnets are now generally used for magnetizing compass needles and also the long and powerful correcting magnets for iron vessels. For experiments on the magnetic field and researches on diamagnetism and magne-crystallization, electro-magnets are nearly exclusively used, not only because of their great power, but also because of the facility with which, by discontinuing the current, or reversing its direction, the magnetism can be produced, or the poles reversed. For convenience, the annexed form is sometimes given to them, and

Fig. 4

sliding pieces of soft iron, called pointed armatures, for approximating the poles, are used where great concentration is required, and a field of very variable force. The electro-magnet is also extensively used in telegraphy. Electro-magnets have likewise been applied as prime

movers of machinery, but not hitherto economically; a circumstance arising from two causes: 1st, while coal, the material used in the production of steam, is found in a state of nature fit for use, the metals and acids from which electric currents are evoked, require expensive and troublesome processes for their preparation; 2d, while it is true that a vast statical pressure is exerted by the magnetic force in keeping the armature in contact with the face of the magnet; yet, on removing the armature, even for a short distance, on account of the rapid decrease of the attractive force, a very great diminution in the effort which pulls the armature back again is experienced. Two or three different modes have been adopted to convert the attraction of these powerful magnets into mechanical action. One of the earliest, is, that of the Rev. Mr. M'Gaughey, a modification of which is presented in the annexed figure.

Fig. 5

The bar of iron B, in the interior of the coil of wire, is rendered magnetic by the passage

of the current, and attracts the piece of iron A, and pulls it down to contact with B, thereby elevating the opposite end of the lever at L, and lifting the bent wire which connects the cups C and D out of the mercury, thereby interrupting the circuit, and thus, destroying the magnetism, and allowing the iron, A, to separate from B, and the lever to resume its former position, which restores the connection of the coil with the battery, and renews the magnetism. The apparatus is thus automatic, and continues to work the lever with a reciprocating motion similar to the motion of the working beam of a steam engine. M. Froment, the philosophical instrument maker of Paris, has several machines of a kind similar to the one just described, at work in his machine shops. In other cases, a bar of soft iron is supported on a vertical axle between the poles of an electro-magnet. The axle carries a

Fig. 6

piece of copper wire of the form of a fork, which dips into a small box, divided into four compartments, two of which, opposite each other, are filled with mercury, into one of which one end of the wire of the coil is dipped, and into the other, the wire from the battery, the other end of the coil being put into permanent connection with the remaining wire of the battery. The mercurial cistern is so fixed that when the iron armature is in the line joining the poles, as is represented in the figure, the forked copper wire on the axle is over the two empty divisions, and continues over them till the armature is turned to a position at right angles to its present one. Then the copper fork comes in contact with the mercury in the opposite compartments, thus transmitting the current from one to the other, and allowing it to pass through the coil and magnetize the iron, which that instant attracts the armature round by both the extremities, closely approximating it to the poles, when the battery connection ceases, and the momentum acquired carries on the armature in its wheeling motion, when again the battery connection is completed, and another impulse is given, till at last a very high velocity is attained, frequently rising to a speed of many thousand revolutions in a minute if no resistance is put on the machine in the way of work to be done. In some cases, many magnets are arranged in a circle, and the iron armatures made to revolve only for a small

part of the revolution under the influence of each when in its immediate neighbourhood where the force of attraction is strongest. This last was the arrangement in the experiment for propelling railway trains, which was, some years ago, made on the Edinburgh and Glasgow line. The inconvenience there experienced was, that, though the force was so great when the iron armature was opposite the magnets as to drag the axes from their places, and destroy the working arrangements, yet, at a short distance from those positions, it was insignificant. Professor Page has recently employed, for producing motion, a modification of an experiment many years ago made by Mrs. Somerville.

FIG. 7.

If an iron or steel wire be placed with one of its ends slightly entered into the interior of a coil of insulated wire, as in fig. 7, it will instantly be dragged in when a voltaic current is sent through the coil, and, it is said, that, if the current be sufficiently energetic, it will remain suspended in the air in the axis of the coil without visible support. Be this as it may, it is certain that it is dragged in with great force, if the current is of considerable energy. Page, in his machine, employs a steel magnet instead of the wire, and by using large coils and magnets excited by powerful batteries, he is able to lift heavy weights through

FIG. 8.

many feet at each stroke of the machine. An apparatus, on this principle, is shown in fig. 8.

Electro-Magnetic Machines: Mechanical Power developed by. An *Electro-Magnet* being easily constructed, capable of sustaining a weight of enormous amount, considering the weight of the sustaining Magnet, and the expense of the battery; and it being easy to shift the attractive to a corresponding repulsive power of equal intensity (see *ELECTRO-DYNAMICS*),—it is not wonderful that sanguine persons early imagined that a motive power had become attainable, uniting the qualities of extreme cheapness, of disposability, freedom from fracture or accident, and almost illimitable in intensity. The form or mode of application too, seemed palpable. Suppose an ordinary armature or set of armatures connected like the spokes of a carriage wheel, and made capable of revolving horizontally, around a point half way between the poles of a horse-shoe *Electro-Magnet*,—it is clear that the opposite ends of each armature would be attracted by the pole nearest it; and if that pole were suddenly changed into the reverse pole, the same armature would be as suddenly repelled.

By attraction then, the spokes of the wheel would be drawn under the poles of the *Electro-Magnet*, and then as suddenly, and with equal force driven away: but as the momentum given by its approach would cause it to tend beyond the pole that attracted it, the substituted repulsion would drive it onwards in the same direction; so that a rotatory motion of the wheel would inevitably result. In this case there is no difficulty whatever in constructing the mechanism: a rotatory motion can be produced at once. See *ELECTRO-MAGNET*. And if this motion had any true or permanent momentum—if it represented in the strict sense a quantity of motion, we should have the element essential to any form of machine. Nor did interesting experiments fail to indicate an apparent possibility that effective mechanisms of this kind might be constructed:—wheels of such sort moving on pivots carefully freed from friction, were made to revolve rapidly: unfortunately a fact was overlooked, which quite incapacitated these rotations to overcome any resistance or do any work;—the power of a magnet to support a weight in contact with it, was confounded in all such expectations with its power to draw towards it a weight at a little distance. But these two powers are utterly different. The efficiency of magnetic attraction diminishes according to the law of the inverse square of the distance of the surface of the magnet and the armature; so that whatever the power to prevent separation when the two are in contact, their mechanical tendency to approach each other deserves little consideration. It is the latter, however, alone, that can induce rotation, or become a source of mechanical effect; so that there is in the very source of this new power, a cause of stagnation, over which no mechanical ingenuity can ever prevail. There are other obstacles in principle—such as the action of induced Electricity during the process; but as the foregoing is fatal, we shall not specify further. The leading Experimenter, or rather Inventor, on this subject was the *Petersburg* (not the *Berlin*) *Jacobi*; and certainly his experiments were conducted on a sufficiently boastful scale. But his submarine boat, before it could be persuaded to move, required the propulsion of eight rowers, the full energy of one of these being consumed on the load or inertia of the Galvanic Battery. Luckily for the "Inventor," it is the policy of the Russian Chancery, that nothing undertaken by the Government shall fail; so that how foolish ever may have been the spectacle of his boat, Jacobi himself reaped consolation in the reward.

Electrometer; generally used indiscriminately with *ELECTROSCOPE*, (q.v.) Accurately, an *Electroscope*, shows the existence of a development of the electric attractions and repulsions; an *electrometer* measures the intensity of the development. The best form of the electrometer in this latter and strict form, is Coulomb's torsion balance, (see art. in page 61) in which if the

fixed ball be electrified the moveable ball diverges, and the angle of divergence can be measured. This instrument is so delicate, that a force equivalent to the dead pull of weight of a grain is sufficient to make the needle traverse the whole circumference; consequently, an arc of one degree measured by the needle, indicates a force not quite three eighths of a grain. The slightest trace of electricity may thus be discovered.—See **ELECTROSCOPE**, **MULTIPLIER**, and **VOLTAETER**.

Electrophorus. An instrument that is often used instead of the electric machine. It consists essentially of two parts, a nonconducting cake and a conducting disc. The cake is of resin, and is contained in an envelope of wood or metal, into which it has been poured in a melted state so that it has a plane and smooth surface. The disc is fused of metal, or of wood covered with tin or metallic foil. Its diameter is less than that of the cake, and its edge is carefully rounded. To the disc is attached an insulating handle, as represented in the figure. To obtain charges from

the instrument we first excite the resin; and this is usually done by heating it with cat's fur, a highly positive electric. The disc is then placed upon the excited cake, and is touched with the finger. It is finally withdrawn by the insulating handle, and is found to be positively electrified. If the disc be now discharged, the experiment may be repeated without a new excitation of the resin, and this may be done hundreds of times in succession, and at intervals of hours or even days apart. When the charges obtained in the disc become too feeble, the efficacy of the instrument may be at once restored by a new excitation of the resin. The theory of this interesting apparatus may be very briefly stated. The development of electricity in the disc is evidently due to inductive action, for the charge obtained in the disc is positive while the originating charge in the resin is negative, and the former charge is stored further by the insulation of the disc when in the immediate neighbourhood of the resin. We find accordingly, that if the disc is touched by the finger or other conductor when it is placed on the cake, it possesses no charge when it is withdrawn, except a barely sensible charge of negative electricity derived by communication. The efficacy of the instrument depends greatly upon the fact, that when the disc is in position it is in circumstances highly favourable to intense inductive action. The whole of the lower surface of the disc is then in closest possible proximity to a well excited body, and the disc is uninsulated. It might be thought that in these circumstances the inductive action would necessarily terminate in discharge; but this result is prevented by the extraordinary power of the resin in retaining a charge once

bestowed upon it. The sensitive power of resin is otherwise proved by several striking experiments, but it is nowhere more clearly evidenced than in the action of the Electrophorus itself, especially in the permanence of its inductive power without new excitation.

Electroscope. In electrical experiment it is as frequently necessary to detect the presence of charges and to determine their species, than permanent instrumental arrangements of different kinds have been made for the purpose, and have found their way into every physical laboratory. Such instruments are called **Electroscopes**. Under all varieties of form they are constructed upon the common principle, that two charged bodies attract or repel one another according to definite laws. The simplest form of electroscope is the electric pendulum, a small and light conducting ball suspended say by a light nonconducting thread. When the ball is charged with a known electricity, it is in a condition to indicate by its movement the presence and species, and to some extent the intensity also, of the charge upon a body brought into its neighbourhood. Another simple form is the electric needle, a light nonconducting lever balanced in the manner of the magnet's compass, and bearing at one end a small body charged with a known electricity. Haff's Electroscope is a simple and elegant instrument of this form, in which the charged body at the end of the lever is a small mass of a particular crystal that may be definitely electrified by pressure for an instant between the fingers, and that retains a charge so bestowed upon it for hours in succession. The instruments that are now generally formed for electroscopic purposes consist essentially of two small and very light conducting bodies that are placed in contact and are free to move to a distance from each other. When the two bodies are electrified, either by communication with the charge examined or by its inductive action, they give immediate signs of this effect by their mutual repulsion. The adjacent cut represents Benoit's gold leaf electroscope, one of the most useful apparatus of this kind, and one that is very generally employed. In this instrument two thin gold leaves of sufficient length are fastened at their extremities between a pair of metallic pins. The pins are prolonged into a metallic stem which passes through an opening in the top of a glass case that envelops the whole apparatus; and the stem is terminated without by a knob of metal. When the leaves are electrified, they diverge to a greater or less extent according to the quantity of the charge. To prevent the contact of the leaves with the sides of the case, a result that would produce great inconvenience, in the working of the apparatus, two uninsulated

conducting balls are placed as in the figure, so that the leaves when greatly divergent come into contact with the balls and are discharged. To examine a body electrically by means of this instrument, we either place the body in contact with the external knob, or merely bring it close to the knob. In the former case the body shares its charge with the knob, and the leaves diverge in virtue of the electricity thus communicated; while in the latter case the given charge acts inductively upon the metallic mass of the knob, stem, and leaves; repels the electricity similar to itself into the leaves, and attracts the other electricity into the knob, so that the leaves will diverge in this case as well as in the former. We can easily determine the species of the charge that produces any sensible effect on the leaves of the electroscope. If the leaves have been electrified by discharge from the given body, let the body be withdrawn; and let a definitely excited body, say a positively excited rod of glass, be brought down from a distance towards the knob. As the rod approaches it will repel into the leaves a continually increasing positive charge; so that if the divergence of the leaves increases under this inductive action, the charge upon the leaves is evidently increasing and was therefore originally positive. If on the other hand the divergence diminishes, the charge upon the leaves must have been originally negative. When the body that we examine is not put in contact with the knob, but only brought near to it so as to electrify the leaves by induction, the simplest way of testing the species of the charge is, first to charge the knob and leaves with a known electricity, and then to bring the body down gradually from a distance towards the knob. The increase or diminution of the divergence will prove here as in the former case, that the charges on the body and in the electroscope are similar or dissimilar. The sensibility of the gold leaf electroscope in its simplest form is very great; and it may be greatly augmented by the use of a condenser instead of the external knob. The instrument in this form is sometimes called the gold leaf condenser. When an Electroscope is so constructed as to measure the intensities of charges, it is called an electrometer. The several forms of apparatus referred to are sometimes employed as electrometers. For this purpose indices are attached to the instruments which mark the extent of the movements of the small charged bodies. None of these instruments, however, can compete as accurate electrometers with the Torsion Balance of Coulomb. For an account of this invaluable instrument, see the article on the **BALANCE OF TORSION**; see also the article on **ELECTRICITY**, especially the remarks upon the **ELECTRIC FORCES** and upon **DISTRIBUTION**.

Electrotype is a new art which has not yet been so extensively cultivated, as it will one day assuredly be. The delicacy of some of its operations with which workmen are not yet familiar,

as well as their powerlessness to manage processes which they do not more than half comprehend, sufficiently explain its present state. Yet in the seventeen years which have passed since its simultaneous invention by Spencer (an Englishman), and Jacobi (a Russian), very much has already been accomplished. The art of Electrotyping has been employed for the reproduction of coins and medals; the copying of stamps and seals, and plaster casts; for obtaining hollow copies of surfaces in relief, and the reverse; for imitating fruits and vegetables; for making moulds for the foundry, reproducing printed characters, copperplates, woodcuts, and daguerreotype pictures, and for copperplate engraving. The mere enumeration of these varied forms of appliance, will at once show the reader how important an instrument in art, a process which has accomplished this in seventeen years, must ultimately become. The process rests upon general rules, which should be followed with great care, and which we shall first indicate, before describing those special precautions that must be adopted. The purpose of it, is the precipitation, by means of a galvanic current, of a metal, from a chemical solution of it, upon a given object in a continuous layer (not, however, adhering to the object), so that this layer may accurately represent the object in all its minuteness and detail. Sometimes it is not meant that what is deposited in this way should come off—that is, the process is employed to deposit a permanent metallic coating upon an object. At other times, it is meant to be removed. The processes for both, with slight variations as to the length of time and the conditions of operation, are nearly identical. Either a simple or a compound pole may be used in the generators of the galvanic current which is employed. In the first, the mould itself forms an essential part of the galvanic current, in the other, it is outside the decomposing bath; the advantage being, that in the latter case there may be attached to the copper pole, a soluble electrode, that is, a plate of the same material as the metal being decomposed in the bath, which itself disintegrates, and nearly makes up for the loss of metal precipitated upon the mould. The first form of the electrotype art, as discovered by Spencer, was this. A square copper plate was put in communication with a zinc plate of the same form and size, by means of a copper wire. The plate was covered with a hot coating of varnish made of unbleached wax, resin and red ochre; and, with a metal point, letters had been traced on the varnish, laying bare the copper. Then a vessel was half-filled with a saturated solution of sulphate of copper, and the copper plate immersed in it; also the glass of another smaller glass vessel (one mouth of which is closed by a plaster of Paris diaphragm), filled with a dilute solution of sulphate of soda, to two-thirds of its contents. The zinc element of the galvanic couple was plunged into this

latter solution, and placed parallel to the plaster stopper, the wire being so bent that the copper plate should also be parallel to it on the other side. The moment that the current was completed, the copper from the solution of the sulphate, became deposited in the furrows made in the varnish, so as to produce the characters in relief. The idea immediately occurred to Mr. Spencer, that this method might be made useful in printing, and he actually employed it for this. It is needless to indicate more minutely—what indeed the whole of this article besides will do—how variously the ideas suggested by this root-phenomenon became subsequently developed. Certain difficulties were met with at the first stage. In overcoming these, new discoveries were made. The first was, that the layer deposited in a moderate time was so thin that it was with difficulty it could be taken off entire. To cure this, Mr. Spencer allowed the plate to stand for a very long time, and he found that instead of the deposit hardening and becoming non-adherent to the plate, it adhered firmly. Here then a new difficulty. If a mould was to be taken in this way, either the layer must be taken off, when too thin to be safely taken off, or if allowed to remain, it must become so adherent, as to injure the original in the separation. The suggested idea of employing moulds taken in plaster of Paris, wax, &c., of the object to be copied, was very natural. In copying a medal—the layer would have been indented where the medal was in relief, and vice versa. In copying the mould from the medal—the electrotypic reproduction would be an exact fac-simile of the original.—We proceed to enter on a few details. We shall not assign names to all the inventions enumerated. The most eminent in the cultivation of the art are perhaps, Messrs. Smee, Elkington, Grove, Mason, and MM. Becquerel, Requillon, Elsner, Solly, Sorel, and Chevalier.

Fig. 1.

weight of water, is poured, and a plate or cylinder of zinc, *z*, inserted. The moulds, *a*, are put in communication with this zinc by a brass wire. As the deposition of copper from the sulphate constantly weakens it, while the pro-

cess goes on, it is best to keep continually supplying the loss by the addition of fresh crystals, or a bag containing them, as *K* in the figure, may be placed in the solution.—An apparatus of M. Becquerel's, manifestly on the same principle, is made of a square wooden triangle, glazed inside with gutta serena, and divided into two compartments by a porous diaphragm, on one side of which is the dilute acid, and on the other, the solution of sulphate. The porous vase *p*, is thus got rid of, and the apparatus is much more easily used. It will be well to keep the temperature between 100° and 160° Fahr.; and as the degree of saturation becomes always unequal in such a process, to turn the box pretty frequently. Another inconvenience comes from the unequal thickness of the metallic deposit, which is always more copious opposite to the point where the mould is attached to the wire. Several conductors symmetrically placed behind, are made use of to remedy this. The origin of another inequality is, that the distance of the corresponding points of the zinc and the mould are not all the same. This can only be remedied, either by giving the zinc the same relief as the mould itself, or making the plaster diaphragm take a suitable shape. The latter method is quite practicable.—The *Compound cell* process as it is called, is, as we have already said, when the current is produced in a vessel different from that in which the decomposing solution is placed. In the annexed figure, *A* is the battery, and *B*

Fig. 2.

the vessel into which the decomposing liquor is poured. The mould with zinc plate corresponding—or, as may be in the compound cell—*copper plates*, which supply the loss of the copper ore, being as in the figure; and the connection established. A yet simpler form is, where there are no cells—but *B* is a mere trough, along which, a metallic rod is laid parallel to its edge, from which rod the moulds are suspended, while parallel to it again, a copper plate, the whole length of the vessel, is dipped into the sulphate; the plate and the rod are then connected with the wires *s* and *z*, respectively. In those batteries, as generally in galvanic batteries, the zinc ought to be amalgamated. The advantages obtained are numerous. There are especially these three—*first*, in that state the metal is not affected by the solution in which it is placed, until the connection is made—*secondly*, the process is very much more regular, in the unamalgamated zinc.

indeed there seem to be certain slight subsidiary electric currents between parts unequally electric, making the process irregular,—currents which besides, (this indicating the *third* advantage,) waste the power, so that not nearly the same equivalent of work (effective or valuable), is obtained from unamalgamated, as from amalgamated zinc. Recent experiments by M. Millen, appear to indicate that some foreign matter will be ultimately discovered, which when present in the solution in very slight quantity, will render amalgamation unnecessary. The simplest process of amalgamation is this. Pour water, pure sulphuric acid and mercury, together into a phial, and then brush with this mixture the surface of the zinc, until it acquires a very bright surface.—For the various kinds of Batteries that are in use in the generators of the voltaic current, reference is made to the article BATTERY, in this Cyclopædia. There is only one, not mentioned there, which is yet little known, but seems to promise very remarkable results. This is the pile of Prince Bagration. According to M. Jacobi's description, it will excel all others in the constancy and regularity of its effect—in the little care needed for its management—and in its own extreme simplicity. It can work for example, for more than six weeks without being touched, preserving perfect regularity of action. Then again, it is so simple in construction, that it may be used and set up anywhere, and its cost is very slight. It consists of a flower-pot, or any other vase impermeable to water: this is filled with earth saturated with a solution of sal-ammoniac, then a copper plate *c*, and a zinc plate *z*, are placed, and put in the earth; and a

Fig. 2.

is good before immersing the copper plate to plunge it into a solution of sal-ammoniac for a few minutes, and to leave it to dry, till decided oxidation becomes visible on the surface. The plates must not be too near, and they must be of such size as to overcome the resistance to transmission which the earth interposes. Several elements may, of course, be used instead of one. M. Jacobi recommends that the different vases should be carefully isolated. The theory upon which the process rests is somewhat obscure;—but, assuming that the apparatus does act as described, there is one very manifest advantage which it has over all the other batteries,—viz.: it gives off no acid exhalation. Those who have wrought at experiments with the ordinary Daniell's or Maynooth batteries,

can appreciate the advantage.—The Baths employed in Electrotyping have now to be described—i.e. the nature of the solution containing the substance to be deposited. We give only a short list of the best. For gold, the following solution may be used: 100 parts of distilled water, 10 parts of cyanide of potassium, and 1 of cyanide of gold. To obtain different shades of gold, we must attach to the picture pole, plates of gold alloyed with silver or copper. The same solution, substituting silver for gold only, serves for silvering substances. We may also have 100 parts of distilled water, 10 of cyanide of potassium, and 1 of carbonate or of ferro-cyanide of silver. Also 100 of distilled water, 10 of hyposulphate of soda, and 1 of chloride or of phosphate of silver. The solutions for platinum are analogous. For nickel, the nitrate or the ammoniac sulphate may be used. For copper, the sulphate chloride, nitrate and acetate (especially for its cheapness, the sulphate). In the case of the sulphate, there is considerable resistance to the current, and the power of the bath is increased by addition of a little nitric or sulphuric acid. When this is the case, the soluble electrode is attacked, and the strength of the solution is increased. If the matter of the mould should be more oxidizable than the copper, it would plainly be unwise to add the acid, so much so, that both Jacobi and Spencer discourage the use of all acid solutions in consequence. The nitrate of copper needs for its decomposition a weaker current than the sulphate, but it is much dearer. The soluble electrode is, in a bath of copper, always of copper. For zinc, the sulphate—for lead, the acetate, very dilute, and acidulated with acetic acid, or a little nitric acid—for tin, a solution in aqua regia acidulated by nitric acid is perhaps the best.—In giving these details, we have spoken very generally. But, four circumstances, which have been noted, distinctly bearing on the success of any proposed experiment; though no clear laws of their action have as yet been arrived at. 1st. The intensity of the pile. 2d. The degree of concentration, and the conducting power of the solution. 3d. Its temperature. 4th. The relative position and magnitude of the two electrodes. M. Boquillon has shown that, as these conditions vary, the deposits of metal may become as hard and brittle as steel, as soft and flexible as lead, or even appear as a powder, or in a crystalline form. As examples, M. Boquillon says that, all other things being equal, if the positive electrode be greater than the negative, or mould, a crystalline deposit will be produced, which may become a powder, if the difference be considerable. The contrary effect occurs if the positive electrode be the smaller. Like effects are produced by a rise of temperature. If we have three cases—the first where the solution is completely saturated, the second where it is less so, and the third where very slightly so, in the first the deposit will probably be hard and brittle, in the

can appreciate the advantage.—The Baths employed in Electrotyping have now to be described—i.e. the nature of the solution containing the substance to be deposited. We give only a short list of the best. For gold, the following solution may be used: 100 parts of distilled water, 10 parts of cyanide of potassium, and 1 of cyanide of gold. To obtain different shades of gold, we must attach to the picture pole, plates of gold alloyed with silver or copper. The same solution, substituting silver for gold only, serves for silvering substances. We may also have 100 parts of distilled water, 10 of cyanide of potassium, and 1 of carbonate or of ferro-cyanide of silver. Also 100 of distilled water, 10 of hyposulphate of soda, and 1 of chloride or of phosphate of silver. The solutions for platinum are analogous. For nickel, the nitrate or the ammoniac sulphate may be used. For copper, the sulphate chloride, nitrate and acetate (especially for its cheapness, the sulphate). In the case of the sulphate, there is considerable resistance to the current, and the power of the bath is increased by addition of a little nitric or sulphuric acid. When this is the case, the soluble electrode is attacked, and the strength of the solution is increased. If the matter of the mould should be more oxidizable than the copper, it would plainly be unwise to add the acid, so much so, that both Jacobi and Spencer discourage the use of all acid solutions in consequence. The nitrate of copper needs for its decomposition a weaker current than the sulphate, but it is much dearer. The soluble electrode is, in a bath of copper, always of copper. For zinc, the sulphate—for lead, the acetate, very dilute, and acidulated with acetic acid, or a little nitric acid—for tin, a solution in aqua regia acidulated by nitric acid is perhaps the best.—In giving these details, we have spoken very generally. But, four circumstances, which have been noted, distinctly bearing on the success of any proposed experiment; though no clear laws of their action have as yet been arrived at. 1st. The intensity of the pile. 2d. The degree of concentration, and the conducting power of the solution. 3d. Its temperature. 4th. The relative position and magnitude of the two electrodes. M. Boquillon has shown that, as these conditions vary, the deposits of metal may become as hard and brittle as steel, as soft and flexible as lead, or even appear as a powder, or in a crystalline form. As examples, M. Boquillon says that, all other things being equal, if the positive electrode be greater than the negative, or mould, a crystalline deposit will be produced, which may become a powder, if the difference be considerable. The contrary effect occurs if the positive electrode be the smaller. Like effects are produced by a rise of temperature. If we have three cases—the first where the solution is completely saturated, the second where it is less so, and the third where very slightly so, in the first the deposit will probably be hard and brittle, in the

second more flexible, in the third formed of a spongy mass of unaggregated crystals, ultimating a black nonadherent powder.—For the *moulding*, or *appex*, any body capable of conducting electricity may be made use of, provided only it be not of such a nature as to be attacked by the solution, and to react on the precipitated metal. A nonconductor may also be used, if we take the precaution to give its surface the faculty of conduction by a very thin layer of a conducting body in a state of powder. The conducting bodies fitted to give moulds are the metals, well powdered charcoal and plumbago. The sulphate of copper, which is the commonest solution made use of, may be affected by zinc, tin, and iron. Hence these metals cannot be used. Platinum and gold would answer perfectly, but they are too dear. There are only left to us silver, copper, and lead, and the alloys of the latter. As silver is precipitated by gold and platinum, it should be used to reduce the metals when the principal deposit is to be very fine. Very fine copper moulds may be obtained by depositing an electro-chemical deposit of the metal on the original piece or plate. Sheet lead suits admirably, being first carefully cleared of oxide on its surface, then smoothed by placing it on a sheet of iron under a press. If the object to be copied be laid with its face to the lead, above the iron, and the press applied, the most delicate copy of the object will be obtained. When the object cannot be submitted to such pressure, other methods require, of course, to be employed. These are the chief metallic moulds. The non-metallic consist chiefly of sealing-wax, soft wax, compound wax, stearine, paper, plaster of Paris, and sulphur. The latter gives very admirable copies of objects, being extremely delicate, but the moment that it touches the precipitated metal, it is apt to combine with it and form a sulphuret. When the plaster mould is obtained, its surface must be covered with something metallic, in order that it may become a conductor. This layer of conducting matter requires to be excessively thin, that it may not alter the relief of the object. This is done either by solutions or powders. In the first case, the surface is washed with a solution from which the metal is deposited either by the agency of light or of some vapour or gas, which takes away the other constituents on being passed over the surface. Sometimes, however, this leaves fissures on the moulds, which destroy the electric conductivity, so that the whole lower half may not be represented. Hence, it is usual to powder the surface rather, and the powders generally used are those of copper and of silver. When the surface of the mould is to be of glass, it is necessary to cover it first with a light varnish, that will lay hold of the conducting powders.—We shall conclude the article by a brief description of various applications of the electrotype process to the arts. *First*. The reproduction of coins or metals. This is done in three ways. 1. The piece is

directly used as the negative pole, after necessary precautions are taken to prevent cohesion. These consist in passing over the original a very thin coating of some greasy substance, as oil, wax, stearine, suet, or the like, and then taking off as much of this as is possible by sucking it up with fine linen cloth. There is obtained by this process an image in hollow, which is again used to give the desired fac-simile of the original object. 2. The impression of the piece is taken on a fusible alloy, so that the first electrotype operation gives the desired relief. 3. The impression is taken with one of those plastic substances which have been before specified. In all the three cases, great care must be employed to prevent the adherence of air-bubbles to the moulds; without this they could not be reproduced in all their delicacy. This is especially troublesome when they consist of glass. To get rid of this, the piece must be examined after it has been for some little time in the solution, and lightly heated, to dispel and disperse them. When only the one face of the medal is to be copied the other must be covered. The *second* application, to the copying of seals and plaster-casts, depends on principles perfectly identical with those last. *Thirdly*, the process is applied to statuettes and bas-reliefs. We regret exceedingly that our space will not allow us to describe the method adopted by Dr. Fau for this purpose. The *fourth* application is to the reproduction of fruits, plants, vegetables, &c. In fact, the actual fruit is just covered with the finest possible layer of metal—in which all the delicacies of nature will manifestly be retained, and then its moisture is extracted first, and ultimately the whole fruit. We shall not do more than allude to the applications of this beautiful art to the purposes of the founder, the electro-metallurgist, the looking-glass manufacturer, the engraver. It has been applied also to the reproduction of photographs and daguerreotypes. Assuredly, in the triumphs which it has already accomplished, there is the highest possible promise for its future.

Elements. The name *Elements*, is given in Astronomy to those numerical quantities that enable us to compute the place of any planet or satellite in the Heavens,—in other words, to compute the size of its elliptic orbit, the position of that orbit in reference to the Ecliptic, and the position of the planet or satellite in its orbit at any given time. Tables of these *elements* as they exist for different epochs, are given in all good treatises on Astronomy; and the mode of using them is familiar to every instructed Student. We subjoin a general Table of the Elements of the chief Planets and Satellites of our Solar System:—for those of the Asteroids, see *ASTEROIDS*. Further reference to details of the subject will be found under the names of the several Planets. The application of such numerical data, is, of course, a deduction from the theory of Gravitation.

Elevation. It is now recognized among geologists that the inequalities of the earth's surface are mainly owing to the agency of some Grand Elevating Force seated at a greater or less depth within its mass. What that Force is, what its origin, and in what manner it is connected with the general Physics of the Globe, are problems whose solution lies beyond the sphere of this Dictionary: but as with Earthquakes, the phenomena of Elevation are being reduced within the sphere of Dynamical Laws; and in so far as these are concerned, it is necessary that we glance in this place, however briefly, at the remarkable and most interesting subject. The true dynamics of geology owe their foundation to Mr. Hopkins of Cambridge. Avoiding all ultimate theories, he rests simply on the fact, that upheavals do take place not of chains of mountains merely, but, as investigation demonstrates, of vast zones, of

which these ranges are the mere accidents; and the question is, whether by aid of the common laws of Force, we may not deduce some general features necessarily characterizing all such dislocations of the earth's crust? Mr. Hopkins' inquiry—now extended over several highly instructive memoirs—has three special divisions. I. The simplest case of elevation is that in which the upheaving force is limited to a small area—say to a point on the earth's surface—its intensity diminishing according to the distance from that point. The upheaval under such circumstances will manifestly be confined to a limited circular region, and must result in what is now well known as a *crater of elevation*. The splits or fissures on the upraised strata will probably be confined to a single system—a system, viz., of long radii from the central point; or there may exist separately or conjoined with the former, another system

dividing the distended soil into concentric rings. The phenomena attending such upheavals had been fully discussed previous to the investigations of Mr. Hopkins, by Elie de Beaumont and Dufrenoy—perhaps with an aim at too high numerical precision—in their interesting memoirs on the volcanoes of central France; where every attainable elucidation is thrown on the phenomena of circular elevations. It ought to be remarked that these species of dislocations seem to have prevailed among the older epochs of the history of the earth: and certainly it has affected most abundantly the existing surface of our satellite. II. The upheaving force, however, instead of being confined within a small district, may be diffused below a large tract or zone: and the simplest mode of considering its operation in this case, is to neglect the shape of that zone, unless in regard to its two dimensions, length and breadth. Now, if such a zone be elevated, it must, during the whole course of its upheaval, be *stretched*, or subjected to *tensions*, which incline to tear or split it; and a little consideration will show, that, (as results from Mr. Hopkins' Geometry) these tensions must reach their *maxima* in two directions; one set inducing the zone to split in the direction of its length, and another acting at right angles to these, and tending to produce fissures along the zone's breadth. Without going farther then, we obtain an insight into the phenomena of *transverse valleys* uniformly characterizing every mountain chain; and the reason is seen why mineral veins are generally found associated in two systems at right angles to each other. A very effective attempt is made by Sir R. Murchison, in his recent Memoir on Scandinavia, to explain the broken-out lines of these northern regions by this prolific principle. But if, in either of these directions, the zone yields in more than one place, it must do so *along parallel lines*. The direction of the *length* of the zone being that of the *maximum* of one set of tensions, it is plain, that whether the zone splits, in obedience to these tensions, in one place or many, the fissures must assume *that direction*, and no other; and as the zone must here be supposed of uniform constitution, it is much more likely that several cracks will take place, than a single one. Nor can there be a doubt that these parallel fissures must occur *at the same moment of time*; for, on the occurrence of one crack by itself, the tension would clearly be relieved; and the only result of a further upheaval would be the mere widening of the first crack, which is now a *line of weakness*. Hence, then, the frequency of the phenomenon of parallel veins, and hence their necessary contemporaneity. There is no difficulty in verifying these deductions, in all the aspects and relations of mineral veins, faults, &c.; and the same physical principles doubtless, overrule that grand series of dislocations treated by Elie de Beaumont. It appears, then, that the contemporaneity of parallel chains crowning the same

zone of upheaval must be taken as absolute and undeniable; but, unfortunately, there are two considerations which prevent an absolute application of the principle; and in which those difficulties originate that are so emphatically indicated in De Beaumont's scheme of systems, by the existence of separate groups, of widely different ages, but with corresponding directions. The first source of ambiguity is in the effect of successive shocks of elevation undergone by the same zone; for though these can create no new fissure, but would simply farther elevate the mountain chains resting over the old ones; they may make, even at a later period, fissures belonging to the oldest shock *visible for the first time*. Mr. Hopkins clearly demonstrates that the cracking of every zone begins on its *lowest surface*, and proceeds upwards; and as it is perfectly conceivable that the first shock may not have completed the split in many cases, or caused it to reach the surface, it is quite consistent with theory, that subsequent shocks, while farther elevating the masses protruded through many splits, may suffice to *complete others*, and rear over them a mountain range, not referable, in so far as dislocations of the neighbouring strata intimate, to the epoch of the first disturbance. Mr. Darwin also inquires what might be the probable effect in strengthening an old fissure, of long intervals of rest, during which the injected rock had intertwined itself with the other beds around it and formed with them one consolidated mass? "Would not," he asks, "the crust in such case yield more readily on either flank, as I believe it must have done in the Cordillera, than along an axis composed of solidified rocks, such as granite and porphyry?" But, besides, the law only holds in the case of mountain ranges *belonging to the same zone*; and there seems no reason to believe, considering the extent of the earth's surface, and the frequency of these oscillations, that *different zones*, with major axes corresponding in direction, may not have been acted on at different epochs. For instance, with regard to that immense area now undergoing subsidence in the coralline regions of the Pacific, is it not probable that its major axis corresponds in direction with the eastern Alps and Himalaya; and, therefore, that such also will be the direction of its system of dislocations? It is far from improbable that the groups in De Beaumont's scheme, which correspond in direction, but differ in age, demand such a solution; and that this is the information they give us regarding the History of the Earth. Like all apparent exceptions to simple and enlarged truths, such ambiguities, while checking the universality of the application of general laws, do not invalidate the laws themselves, but only inform us better of the circumstances within which they have operated. III. Mr. Hopkins next surveyed a case in which the resulting phenomena might be supposed modified by the shape of the upraised surface; and probably his application of

general principles to the specialties of the Wealden, is as complete a triumph as any inquiry of this kind can be expected to accomplish in theoretical geology. The deductions having quite outrun observation, Mr. Hopkins re-surveyed the Wealden, with a view to the detection of its dislocations; and his theoretical chart might almost be taken as an accurate map of the country. Now, in this application of the theory, there is an achievement quite beyond any mere probable explanation of the *law of parallelism*. This law, although still the prevailing one, is interfered with and subjected to great modifications by the *steps of the district*—modifications, however, of a fixed and determinate nature, flowing from the same actions which caused the law of parallelism itself; and every predicted deviation of the lines of fissure or dislocation from rectilinearity and accurate parallelism, as well as every predicted new relation of the transverse lines to the longitudinal ones, agrees—to an exactness altogether remarkable—with the facts elicited by a careful scrutiny of the region.

Elevation (Angle of). See DEPRESSION.

Elimination, a process so important and comprehensive, that it may be said to constitute the whole of analysis. Every research in analysis may, indeed, be put under the form of a problem to be resolved. Equations between certain quantities are presented—portions of which are known, the others unknown,—the values of these last being the *quæsitæ*. Now the object of analysis is to extract the required value from these equations; in other words, to *eliminate* the quantities that at first rested unknown. Until comparatively recently, the methods of elimination were simple, elementary, and often only tentative: the subject has now grown into a large and profound theory, containing within it some of the subtlest speculations of the modern Algebra. In our article EQUATIONS, certain of the more interesting portions of this inquiry have been exposed; but space would not permit a full appreciation either of its extent or remarkable generality. Under POLYNOME, we shall give as detailed and satisfactory an account as the nature of this work will allow, of several researches of the modern Algebra, such as DETERMINANTS, with which the theory of elimination is now intimately connected; and very faintly would we have entered in this place on a special and systematic glance over the whole subject. This, however, is rendered impossible, in the meantime, by other exigencies of this work; and, although most unwillingly, we must simply refer the student to such works as the *Algebre of Lefebvre de Fourcy*, of *Bourdon* (latest edition), of *Serret*, &c., and more particularly to the distinct and very able treatise of *Faà de Bruno*. The only substitute we can at present offer is a mere enumeration of the contents of Bruno's volume; these contents will at least indicate the sphere, and show the boundaries of the doctrine of elimi-

nation as it is now understood. Bruno arranges his treatise into three great chapters, whose subdivisions are mainly as follows:—I. THEORY OF ELIMINATION FROM TWO EQUATIONS. (1.) *On Symmetrical Functions of the Roots and their Properties*. (2.) *Elimination of the Variable from two Equations with one Variable*.—Definition of the resultant; different modes of elimination by aid of symmetrical functions of the roots; methods by which the resultant is sought for as that of a system of linear equations; method of the greatest common divisor; method of Bezout; method of finding the resultant by considering it as the *discriminant* (see POLYNOME) of a function of the second degree; formation of polynomial multipliers. (3.) *Properties and Uses of the Resultant*.—II. THEORY OF ELIMINATION IN THE CASE OF THREE EQUATIONS WITH TWO VARIABLES. (1.) *Properties of the Solutions common to two Equations with two Variables*.—Number of common solutions; degree of the final equation when the two equations are not canonical; method of *Liouville* for developing an implicit function into series; calculation of symmetrical functions; theorem of *Jacobi*. (2.) *Elimination of the Variables from three Equations with two Variables*.—The resultant formed by means of symmetrical functions; method of *Bezout*; method of *Sylvester*.—III. GENERAL THEORY OF ELIMINATION. (1.) *Properties relative to Common Solutions*.—Symmetrical functions of common solutions; theorem of *Betti*; *Bezout* on the degree of the final equation; method of *Liouville*; theorem of *Jacobi*; number of independent solutions. (2.) *Research and Formation of the Resultant*.—Formation of the resultant by aid of symmetrical functions; method of *Bezout*; method of *Sylvester*. (3.) *Properties of the Resultant*.—If the English student can learn nothing else from the foregoing bald list of contents, he may at least learn this—how wrong it were for him, in the present condition of science, to rest satisfied with a knowledge of what once passed current as an account of the *Theory of Elimination*.

Ellipse. One of the well known conic sections. Unlike the parabola and the hyperbola, it is a re-entering curve: on one side its limit is the circle, on the other the parabola. The equation of the ellipse referred to its centre is—

$$\frac{x^2}{a^2} + \frac{y^2}{b^2} = 1,$$

where *a* and *b* are the major and minor semi-axes. The student should consult *Salmon's Conic Sections*.—Of course it is universally known, that the ellipse is the curve in which our planets move.

Ellipsoid. If we imagine an ellipse to revolve round either its major or minor axis, and suppose that each successive ellipse so formed in space be marked down, the resulting surface will be what is called a *spheroid*. As we have already

seen that every circle is a sort of ellipse, the spheroid is a kind of ellipsoid. As the earth is of a spheroidal form (FIGURE OF EARTH), the properties of the spheroid, and of its generic surface the ellipsoid, are of the greatest physical importance. The technical expression for the ellip-

soid, referred to its centre is $\frac{x^2}{a^2} + \frac{y^2}{b^2} + \frac{z^2}{c^2} = 1$.

Ellipticity. The proportion which the excess of the larger semi-axis of an ellipse over the smaller, bears to this smaller axis. It is not the same, therefore, as the *eccentricity*. Its value as technically given is $\frac{a-b}{b}$.

Elongation (Angle of). The angle measuring the distance between two stars as seen from the earth. It is the angle made by the lines drawn from the eye to each star respectively. Custom applies it only to the case of bodies in the solar system; and still further confines it, in almost every case, to a planet and the sun. We thus speak of the elongation of Mercury,—i.e., its distance from the sun, and instead of the elongation of two fixed stars or planets, we use the word "*distance*."

Emergence. The reappearance of one heavenly body from behind another after an *eclipse* or *occultation*.

Empirical Law. If, on the contemplation of a number of separate facts connected with the same subject, the inquirer discerns some external relationship expressible by a simple term or proposition, that term, or theorem, is called the Empirical Law of these facts. For instance, Bode's Law of the Distances of the Planets from the Sun, would, were it correct, be an Empirical Law: in the same way in Physics, multitudes of facts are connected and expressed by general terms, or *Empirical Laws*. These Laws may be termed the rudest and rudimentary steps in the process of generalization; and they often lead to the discovery of Higher Laws, or Laws that connect the whole range of subordinate phenomena with some wider scheme of sequences. These latter laws appear *causative*: the former never are so.—Empirical Laws may frequently be most easily detected by GRAPHIC METHODS, to which article the student is referred.

Energy.—Energetics.—The term *Energy*, in its larger and only true sense, is the capacity to effect changes; and if any general laws can be predicated of Energy as such, these laws must be applicable to, or dominate over, every branch of Physical Science, and express the order and mode in which changes are effected. Hence the idea of a pure and abstract *Science of Energetics*—a science which, if constituted, would be the highest *abstraction* or *generalization* attainable in *physical research*. For the first attempt to lay the basis and sketch the probable course of such a generalization, science is indebted to Mr. Macquorn Rankine,—a sketch which must be ranked

among the most important of our numerous and emphatic indications, that Physical Science is about to enter on a fresh and vigorous career. The reader is earnestly referred to a paper on the *Science of Energetics* in the *Edinburgh Philosophical Journal* for July, 1855. See also HEAT and POTENTIAL.

Engine. A name given to a mechanical contrivance, by which any physical power is applied to produce any given physical effect. The difference between the words *engine* and *machine*, is not at all a definite one: oftentimes the words are used indiscriminately. For a notion of certain general theoretical principles applicable to the construction and play of Engines, see MACHINES.

Engine, Air. See AIR ENGINE.

Engine, Calculating. We shall speak briefly in this place of that class of machines which have been proposed for the execution of calculations and other mathematical operations.—It is, of course, wholly impossible to endow any mechanism, however ingenious, with the power of *thought*, or the ability to originate: but without intrenching on this inaccessible sphere, there are duties no less extensive than onerous, which it quite falls within the scope of mechanical contrivance to perform. Let an operation be *definite*, or have a fixed order, then—no matter for its complexity—we have seen enough to know, that some combination of motions and processes may be imagined, that might undertake and determine it: the results of existing manufacturing genius should establish that there is at least nothing wonderful in the conception, that an engine can be contrived capable of relieving the scientific inquirer of much, if not of all that tedious but pure manipulation with figures, in which his time and energies are at present so largely consumed. Recently, for instance, we have had a very successful *Arithmometer*, by M. Thomas, of Colmar, by which all ordinary arithmetical calculations are executed without fatigue to the operator: and again, the machine just exhibited before the Royal Society, by M. M. Schentz, which—resting on the principle of *Differences*—is able, on the turning of a wheel, to give the successive terms of any *series*, whose law may be confided to it. The machine of these very excellent Swedes likewise *prints* a large part of its results, and thus still further provides for the accuracy of its tables. But while giving all honour to these and other gentlemen, it were equally unjust and unbecoming to refrain from naming as the instigating and guiding genius in this remarkable career—our countryman, Mr. Babbage. Mr. Babbage's achievements—not *projected* merely, although not yet *realized* achievements—are twofold. I. In the first place he perfected a *Difference Engine* of very comprehensive powers. On referring to our short article on DIFFERENCES, the reader may have it re-

called to him, that any series—be the relation uniting its terms as complex as it may—will in the end yield a certain order of Differences that shall be 0. The complicity of the relationship merely affects the *order* of those differences which becomes 0—the more complex the relationship, the *higher* that *order*. Now, Mr. Babbage's enterprise was this,—he undertook to construct an engine capable of managing series so complex, that the differences of its terms do not reach zero until we ascend to the seventh order: or in analytical language, he undertook to manage the *integral*, defined by the equation

$$\Delta^7 \phi z = 0.$$

and this holds where $\phi . z$ contains no power of a variable higher than the sixth; or when

$$\phi . z = a + b x + c x^2 + d x^3 + e x^4 + f x^5 + g x^6.$$

An immense range of nautical and astronomical tables lies within the limits now defined; but, still further, while an engine with such capabilities, commanded everything within its grasp accurately and completely, it also tabulated approximately, or, between intervals of greater or less extent, any series whatsoever, that could be treated by the *Method of Differences*. Referring, again, to our short article on DIFFERENCES, the student will see that the hope to succeed in such an enterprise, how novel soever it appeared, was not chimerical: it rested on this only, that an engine could be made capable of performing at command all operations of addition. The chasm between the idea and the realization of it, is in this case vast indeed; but we believe that it has been universally conceded, that all practical difficulties had yielded to the genius of Mr. Babbage.—II. During the process of the construction of the *Difference Engine*, Mr. Babbage's views enlarged—probably in so far through his growing familiarity with the capabilities of machinery; and a new, and much more gigantic conception arose before him in perfect definiteness. If an engine could be constructed to perform, at command, the process of addition, no reason seemed to exist why one might not perform the whole of the elementary changes to which quantity can be subject, viz. addition, subtraction, multiplication, and division. But all changes that can be produced on quantity, in other words, any development to which quantity can be subject, are mere combinations of these: so that an engine capable of performing these at command, might become an instrument to execute any development whatsoever. And such an instrument is the proposed *Analytical Engine*. Without stopping to describe the machinery, we shall take it, as a fact accepted everywhere, that Mr. Babbage devised the means of executing *directly* all elementary operations. And the next requisite was, that he should be able to cause his engine perform all these, according to *any special order*,—or what is the same thing, to develop any function whatsoever, whose

law of development is ascertained and fixed. To obtain a clear conception of the mode in which he realized this object, it is necessary that the reader have in his mind a distinction, already of vast value in Analytic Science, and exemplified everywhere in our industrial mechanisms—the distinction, viz. between the operations to be performed, and the quantities or substances operated on. An *operation*, is the method, or the *law* according to which some object or material is to be changed; and is perfectly distinct from consideration of the material or object itself. Can an engine be made, then, so that it be adjusted to the performance of any order of operations, however complex,—so that, whatever its abstract capacities, it may, at any time, be constrained to work according to *some fixed law or order*, to the exclusion of every other? Suppose the zero, or neutral state of the *Analytical Engine*, to be a mere expression or possession of capability to execute all the elementary and essential changes on quantity, can it be adjusted to perform these according to a fixed law, or what is the same thing, to *develop any function*? The answer has been practically given by the JACQUARD LOOM. In this case, the *cards*, oblige a machine, in which there really is a latent power to work any pattern—to work out one particular pattern: and Mr. Babbage saw, that, in the same way, a peculiar and appropriate set of *cards of operation* might compel the calculating machine, to act for the time, according to one certain fixed law and no other. The wonderful results of the *Jacquard*, illustrate the amazing comprehensiveness of this principle; and it may further assist our conceptions if we liken the *numerical* or other quantities, which form the subject-matter of the functions, to the *material* on which the Jacquard mechanism works. These *numbers*, or *subjects*, are introduced into the Analytical Engine by arrangements quite independent of those which regulate the *operations* to which they are to be subjected: the two, in fact, work independently, although harmonizing throughout; and the result of the two is the reproduction of the matter,—introduced in a *raw* state—in the shape of cloth with the pattern woven. It is clear, too, that the matter or things acted on need not be *numbers*: such an engine could undertake any problem concerning *objects* whose natural fundamental relations can be expressed by the relations $+$, $-$, \times , and \div :—for instance, if the fundamental relations of pitched sounds were susceptible of any similar expression, the Engine would be capable of *weaving* elaborate and scientific pieces of music of any degree of complexity or extent.—On the details of the mechanism of the *Difference Engine*, the reader will find a very instructive paper in the *Edinburgh Review* for July, 1884; and a much more comprehensive and generalized description of *both*, in an exceedingly precise memoir by M.

Menabrea, of Turin. A translation of this memoir, accompanied with very remarkable notes, from the pen of the late Lady Lovelace—Lord Byron's accomplished Ada—appeared in the third volume of *Taylor's Scientific Memoirs*.—It were unjustifiable to conclude even this brief notice, without an expression of profound regret that circumstances of any kind should have induced Government to suspend the realization of great works like the foregoing,—works which a Government alone could realize, and of which any Government might well be proud. It is gratifying to notice, that in a spirit of fullest justice to Mr. Babbage, and under deep sense of the public importance of what is at issue, Lord Rosse took occasion, on his vacating the chair of the Royal Society, to make a reclamation on the subject, which every scientific man will join in hoping may have its deserved success.

Engine, Locomotive. See LOCOMOTIVE ENGINE.

Engine, Steam. See STEAM ENGINE.

Engine, Thermo-dynamic. See HEAT, § 22, &c.

Engineering. That department of science which may be termed the Science of Engineering, is defined most accurately as follows. Every one conversant with mechanics, knows that the abstract truths of Statics, Dynamics, &c. cannot be represented in any actual case of equilibrium or in the working of any machine: in no case in nature, for instance, do we find a pure mathematical line or circle; so, likewise, in no case do we find the perfect expression of pure or rational mechanical truth. And the cause is this:—instead of working, in nature, with *ideas*, or *hypotheses*, we work with materials having certain properties or qualities of their own; and it is only through these instruments, with their peculiar and essential qualities or characteristics, that Static or Dynamic theorems can be presented in practice. It becomes, therefore, a question of the last importance, in what manner must these qualities of our instruments, modify the action of our pure theorems; and how must we take account of such inevitable modification, before applying these theorems? The reply to which question is the end and aim of the true *Science of Engineering*. Unfortunately, it cannot be said that any such Science has hitherto been methodized; although, in the constructions and writings of our famous engineers and architects, there are abundance of valuable contributions towards its various departments. The object of the present *Cyclopædia* does not expressly include this wide sphere of inquiry; and it is to be hoped that the publisher may be induced to undertake as a separate and express work—the *Cyclopædia of Practical Mechanics and Engineering*. Nevertheless, it is not possible to draw an absolute line of demarcation; and certain considerations more suitable to the other work, are touched,

under such articles as ELASTICITY, FORCE, FRICTION, MACHINE, ROTATION, STRENGTH OF MATERIALS, &c. &c.—There are now, among most civilized nations, regular and organized corps of scientific men pursuing, in various ways, the calling of engineers,—such as *Architects*; *Civil Engineers*; *Military Engineers*; *Engineers of Mines, of Roads and Bridges, Railways, &c. &c.*

Epact. The number of days after the beginning of the year, when the new moon takes place. It is used in all our almanacs for this. Suppose, for example, 12 be the epact of this year, then the new moon will come on the 12th of January, and by adding 29 and 30 alternately, we get the dates of all the new moons throughout the year thus. Then, for next year, we add 11 to 12, because 11 is the difference of the days in the year 365, and the days of the 12 lunar months 354. We obtain thus 23 as the epact for next year. Add another 11 and we get 34. Now, if the first lunar month of that year be to be taken as 30 days, then 4 (34—30) will be the epact, and so on. For the year immediately succeeding leap year, we must add 12 (366—354).—The system of epacts has many curious and somewhat puzzling details which we do not require to describe. It is chiefly in use for determining the date of Easter and of the church festivals depending on it. It is of Greek origin. A very interesting account of it will be found in Delambre (*Astronomie Moderne*, i. 4-82).

Ephemeris. A species of almanac of extensive use to navigators and astronomers. To the former it is a matter of the utmost importance to determine their exact position on the globe. He can do this, as we shall see (LONGITUDE and LATITUDE), by sextants, chronometers, and other methods of direct observation. But all of these are liable to very many errors, and require to be corrected one by the other, leaving no complete certainty on the mind after all. His Ephemeris, or as in this country it is more commonly termed *Nautical Almanac*, tells him, however, the exact position for every hour of every day of most of the heavenly bodies, gives him the exact moments of eclipses of satellites, the amounts of lunar distances, &c. &c. for the standard position—that of the Greenwich observatory in this country. He observes them from his own position, and calculates it from the observation. For the astronomer it is equally important. Many phenomena can now be so calculated that we shall thus know them better, than we can by observation. They depend upon general laws admitting of mathematical statement, and therefore we can infer the exact date of the phenomenon, the true position in which it will place some visible object, and such like. The knowledge of this, as directing the astronomer when to observe, and how, would be of very great importance, but it becomes of still greater importance in another light. He does actually

observe the phenomenon, under, for example, the disturbing influence of *refraction*. He gets the exact position calculated mathematically from his almanac, and he finds the apparent position from his observation. The difference of the two is due to this influence of refraction, and he tabulates that. From a series of such observations, he can find the laws which that influence follows, and can correct those observations which cannot be predicted, in which this same disturbing influence operates, so as to arrive at the true phenomenon which he wishes to observe. If, as is often the case, in any given observation on the phenomena calculated by the almanac, several causes of error act, the resultant difference will be due to them all, and he will have, after tabulating these differences, to adopt the method of **ELIMINATION** (*q.v.*) to arrive at the values of each by itself. The French nautical almanac, *« Connaissance des Temps*, is the best known of the foreign ones.

Epicyle. The notion that uniform and circular motion inheres in all bodies so grand as the celestial ones, was a source of considerable trouble to the ancient astronomers. They resolved to cling to it whatever came of it; and they had to make some artificial physical hypothesis to support its credit. One discrepancy has been already accounted for (see **ECCENTRIC**), but a greater remained. It was found by very ordinary observation, that the planets appear—instead of moving in a circle—in fact to move in a very extraordinary line without any apparent regularity. The inventive Greek mind surmounted the difficulty in this way. The planet moves in a regular circle, the centre of which regular circle moves uniformly and circularly itself round the eccentric (*q.v.*) in which we are. Thus (see fig.)

the planet *P* may move in the small circles indicated, the centres of which circles move along the larger circle *D.R.* Here, though the general motion of the planet be unquestionably forward, we can still understand how at

one time it should take a turn backwards and again progress, then go forward more rapidly, then appear to stand still, and may change, at once the direction and velocity of its motion, in all imaginable ways, simply by a proper adjustment of the rates of these two motions, viz., of the planet in the circumference of the small

circle, and of the centre of that circle, along the circumference of the large one. The figure will show a case, where a general forward motion, from *o* to *o'* will appear to the spectator at *E*, to be in reality a backward motion from *P*, where the planet really is at the time that the centre is at *o*, to *P'* where it is when the centre is at *o'*. All varieties of motion might be similarly produced.

Epoch. The date of some memorable event in the history of the world, from which nations reckon their time;—the commencement of an Era. The Christian era commences at the epoch of Christ's birth; and the Mohammedan, at the date of the Hegira.

Equation, Differential (Technical). The theory of differential equations, is an extension of the integral calculus, in which it is required to find the function whose differential, with regard to a variable, is known. In some cases we have given, the differentials of higher orders, the second, third, fourth, &c., and we are required to find the function corresponding. The subject has not been yet so fully considered as it ought from its importance. A differential equation is expressed in such a form as this, $\frac{d^2 y}{dx^2} + \frac{dy}{dx} = x$, where *y* is a function of *x*,

which it is required to discover. In $\frac{dy}{dx} = x$ we

have a problem of the integral calculus—a mere case of this. See **CALCULUS**.

Equation, Lunar. A perturbation of the moon. See **LUNAR THEORY**.

Equation of Centre. The motion of the earth round the sun is seen by us exactly as if it were an equivalent motion of the sun round the earth. If the earth moved round the sun with a uniform circular motion, we would suppose the sun to do the same round the earth. It does move, however, in an ellipse, describing equal areas, in equal times, and so does the sun appear to move. This ellipse, however, varies very little from a circle. In uniform circular motion we could readily tell the direction of the visual ray and the change of direction—in fact, determine the longitude of the sun and its changes. In any number of days the same fraction of 360° of angular space would be described, as this number of days is of the complete year. The closeness of the actual ellipse to a circle makes it convenient for us to calculate what would be the position of the sun if this were the true state of the case, and to tabulate the differences from this result, which actually exist. How these differences arise, we can understand. Suppose *P P* to be the sun's apparent or the earth's real orbit, and *s* the central orb in the focus of the ellipse. Let *A M* be the axis major and *M S P'*, *A S P* be two equal angles. Then, according to the hypothesis of uniform angular motion the spaces *M S P'*, *A S P* should be described in

equal times. But, according to the facts of the case, they will not be. $\triangle MSP'$ has a much larger area than $\triangle ASP$, and will therefore take longer time to be described. The sun will there-

fore appear to move slower at $P'M$ than at SP , and in consequence of this inequality, it will happen that the mean longitude would make the visual ray perhaps take the direction SP'' while the actual direction is SP' . The angle $P'SP''$ is called the *equation of the centre*. The motion at A is thus more rapid than the average motion. This excess above the average increases from A onwards by new additions, until the body P reaches such a position as P'' . There the motion is just about the average motion, but still the *true place* is much in advance of the *mean place*, though that advance now ceases to increase and begins to diminish, lessening the excess gradually until it vanishes, and the *true* and *mean place* coincide. Where there is the greatest difference between the *mean* and *true place* of the earth, or apparent place of the sun, this difference (e.g. the angle $P'SP''$) never exceeds $1^\circ 55' 38'' \cdot 8$. In case of the motion from A to M , its amount is to be added to that of mean longitude—in the other, from M to A , to be subtracted; at M and A , it will be nothing.

Equation of Differences (Technical). An Equation of Differences is such as this;—required a function of x , such that the difference between it and the same function of a number larger than it, whatever it may be, say by 1, shall differ by 1. This equation would be so expressed,

$$\phi(x+1) - \phi(x) = \phi(x) + 1.$$
 Required $\phi(x)$. These equations of differences have been of immense importance in the history of recent physical science. All our more valuable theories are based on them; and from solutions of them, a great many of our most beautiful recent discoveries take their origin. See DIFFERENCES.

Equation of Equinoxes. The motion of the equator along the ecliptic, which is distinguished by the name of *precession*, is like those of which we have been just speaking, an alternating one—sometimes faster, sometimes slower, and returning in a cycle constantly to the same degrees of velocity. Taking the motion then as

uniform, we calculate the position of the equinoxes on the ecliptic, and tabulate the amount which must be added to or subtracted from that calculated result, to give the *true position* of the equinoctial point. This difference is set down in tables as the *equation of the equinoxes*. A table of these differences will be found at page 242 of the *Nautical Almanac* for 1854, which may give the reader a notion of the amount of these variations. The position of the equinox is given by it for every ten days, during which interval, the alteration of rate is not of importance, and can be calculated.

Equation of Time. It has been already frequently noted that there is a difference between the lengths of the mean day and the apparent day. If the actual apparent day—the interval between the sun's successive transits of the meridian—were of uniform length, the apparent and mean time would be the same. But the simple mechanisms which we can construct as measures of time give measures merely of successive *equal* intervals, and cannot be brought except by most complex machinery to coincide entirely with the solar motions. Yet it is convenient that the two methods of measuring should be coincident as much as possible; and for that purpose the interval which clocks and watches are set to measure, is the mean of the solar days for a year or a century or an epoch. The causes of this inequality in the length of the solar day are due to all the “equations” which affect the regularity of the earth's motion round the sun. Those have been already referred to. They express different velocities and different spaces during the same intervals of time, of the sun's proper motion (as it appears to us) among the stars. In one day, for instance, he may move, say $1\frac{1}{2}$ degree backward, and in another, say only $\frac{1}{4}$ degree. These irregularities have considerable effect in causing the difference of mean and solar time.—Another cause is the obliquity of the ecliptic. If the equator and ecliptic coincided, the exact amount of motion in longitude of the sun would be, each day, represented fully in the apparent day. But as they do not, but form two separate circles having a definite inclination and a changeable one also, the reader acquainted with trigonometry will see that there cannot be the same amount entering, at different times, into the valuation of the mean day. At one time, the motion is parallel nearly to the equator—at another, differently inclined to it. At one time, the sun in his motion is going towards the equator—at another, from it, and these differences will be readily conceived to occasion our connecting different parts of the real amount of change of longitude (or apparent solar motion), with the apparent solar day. To remedy this a fictitious sun is supposed to move in a circle parallel to the equator (cutting the meridian at right angles always, instead of with a constantly varying obliquity), and the dif-

ference between its hypothetical motion and the real motion of the sun in the ecliptic, is tabulated. The whole of these equations are put together, in the equation of time. Its object thus is, to enable us to adjust the mean noon, measured by our clocks and watches, with the true noon regulated by the sun. Tables of it are found in the nautical almanacs; its amount is sometimes pretty considerable. Sometimes the apparent noon is $16\frac{1}{2}$ minutes before mean noon, and sometimes $14\frac{1}{2}$ minutes behind it.

Equations, Algebraic.—It will be assumed throughout this article that the reader knows the elements of algebra, at least up to quadratic equations and the binomial theorem. All equations involving one unknown quantity x , may be comprehended under the general form—

$$f(x) = \phi(x);$$

where $f(x)$ and $\phi(x)$ denote functions of x , that is, quantities or expressions derived, in a more or less complex manner, from x and given numbers. It should be observed at the outset that this technical form of statement, $f(x) = \phi(x)$, admits of two meanings, perfectly distinct from each other, and so far indicated by the terms *identity* and *equivalence*. First, The expressions $f(x)$ and $\phi(x)$ may be one and the same; or they may be reducible to one and the same, by the performance of operations merely indicated. To assert such a relation of $f(x)$ to $\phi(x)$, mathematicians employ the form of statement $f(x) = \phi(x)$, which is therefore called, in such cases, an *identical equation*. The following are examples:—

$$\begin{aligned} x + 5 &= x + 5, \\ 2x + 7 - (x + 4) &= x + 3, \\ (x + 3)^2 &= x^2 + 6x + 9. \end{aligned}$$

Evidently the quantity represented in any identical equation by the general symbol x may be quite indeterminate: the equation holds for all values of x . With equalities of this kind we shall have nothing to do in what follows, except as means of investigation. Secondly, If the functions $f(x)$ and $\phi(x)$ are not identical, they will be generally unequal when a certain value is assigned to (x) ; but for some particular value or values of x , the functions may be equal to each other. To assert this relation of equality between $f(x)$ and $\phi(x)$ for a particular value or values of x , mathematicians employ still the form of statement $f(x) = \phi(x)$, which, in such a case, is called simply an *equation*: and by a *root* of the equation is meant any quantity, positive or negative, arithmetical or literal, real or imaginary, which, when substituted for x , satisfies the equation, or verifies the statement of equality. By the *resolution of an equation* is meant the determination of its roots: this is the main inquiry in the theory of equations, and one to which all other questions upon this subject are subordinate. By transposition of terms, every equation involving one unknown may be reduced to the form

$F(x) = 0$, where $F(x)$ is a function of x . The equation is called *algebraic* when $F(x)$ is an *algebraic function* of x , that is, an expression derived from x , in combination with given numbers, by *algebraic* operations alone. In the study of algebraic equations, it is generally found convenient to reduce them, or to suppose them reduced to the following form:—

$$\left. \begin{aligned} x^n + p_1 x^{n-1} + p_2 x^{n-2} + \dots \\ + p_{n-1} x + p_n = 0 \end{aligned} \right\} (1.)$$

As distinctive of which form let these facts be remembered: the second side of the equation is 0: on the first side the powers of x are arranged in descending order, the indices diminishing by unity from term to term, beginning with the whole number n , which measures the degree of the equation: the coefficient of x^n is + 1: the following coefficients $p_1, p_2 \dots p_n$, are all given numbers, any one or more of which may = 0 in particular cases. We shall often refer to the above equation as the eq. (1): we shall sometimes represent its first member, for brevity, by $f(x)$: sometimes also we may have to speak of $f(x)$ as a *rational integer function* of x ; meaning by this that $f(x)$ is the sum of a series of multiples of powers of x , including generally a term, (such as p_n) independent of x , but excluding all powers with negative or fractional indices. Whatever be the form in which an equation is proposed, or in which it presents itself as the algebraic translation of some actual question, it may always be reduced to the form (1) by such operations as the transposing and collecting of terms, clearing of fractions, clearing of radicals, dividing by the coefficient of x^n ; and as these operations are generally of the most elementary nature, we shall refer to them no further. A brief exposition of this very wide subject will now be attempted, under the three following heads:—First, the general theory of algebraic equations. Second, the resolution of numerical equations, or of equations whose coefficients are given arithmetically. Third, the resolution of algebraic equations, that is, of equations whose coefficients are represented by letters, and therefore left indeterminate.

I. THE GENERAL THEORY OF ALGEBRAIC EQUATIONS.

1. For a moment, let us consider $f(x)$, or the first member of eq. (1), apart from the condition of its equality to 0. If we assign any value to x , it is evident that $f(x)$ will assume one definite value; if we assign a second value to x , $f(x)$ will assume a second definite value, and so on. It follows that $f(x)$ *varies in value along with x , according to a perfectly definite law*; and we may observe in passing, that it is this and this alone which is implied in the name *function of x* . The study of the law of simultaneous variation of $f(x)$ and x belongs properly to the differential calculus; but there are a few notions upon

EQU

the subject that are indispensable in the discussion of the elementary properties of equations. Suppose then that x is changed into $x + h$; the successive terms of $f(x)$ are changed into $(x + h)^n, p_1(x + h)^{n-1}, \dots, p_{n-1}(x + h), p_n$: and these terms may be developed in series of ascending powers of h , by the binomial theorem, as follows:—

[illegible]

We obtain the value of $f(x + h)$, or the new value of $f(x)$, by adding all these quantities; adding by columns we find a result, of the form

$$f(x) + Ph + Qh^2 + Rh^3 + \dots + h^n:$$

where the coefficients P, Q, &c., are independent of h . The full expression for P is—

$$n x^{n-1} + (n-1) p_1 x^{n-2} + (n-2) p_2 x^{n-3} + \dots + p_{n-1},$$

which the more advanced reader will recognize as the *first differential coefficient* of $f(x)$, by which name we shall refer to it hereafter. But observe that the first diff. coeff. of $f(x)$ is defined here to be *the coefficient of the first power of h in the development of $f(x + h)$ in a series of ascending powers of h .* Observe also, from the above expression for P , that to find the diff. coeff. of the first member of eq. (1), *we multiply each term of that member by the index of x in the term, and then diminish the index of x by unity.* These elementary notions will be of use hereafter. Returning to the development of $f(x) + h$, we observe that if the increment of x be h , that of $f(x)$ is—

$$Ph + Qh^2 + Rh^3 + \dots + h^n, \text{ or } h \{P + Qh + Rh^2 + \dots + h^{n-1}\}$$

Now the successive coefficients $P, Q, R, \&c.$, are finite when x is finite; this is evident from their composition in terms of x and a : and therefore the quantity within the vinculum in the last expression (while it may be in some cases positive, in others negative, in others nothing) *cannot be infinite* when x and h are finite. It follows that the increment of $f(x)$ is, at most, a finite multiple of the increment of x : and therefore, when the increment of x is very small, that of $f(x)$ is also very small; and the two increments vanish together. Hence, when x passes from one finite value a to another finite value b , *continuously* (that is, by an infinite succession of increments, each infinitely small), then $f(x)$, or the first member of eq. (1), passes *also continuously* from the value $f(a)$ to the value $f(b)$. This conclusion, that $f(x)$ is a *continuous function* of x , would require more space for its proper

EQU

illustration than may be here given to it; but the only deduction from it that we shall have occasion to apply is perhaps evident enough from what precedes. It is this, that if $f(x)$ be positive when $x = a$, and negative when $x = b$, or vice versa, then there is at least one value of x between a and b for which $f(x)$ equals nothing. In proof of one other property of $f(x)$, consider a series of multiples of descending powers of x , such as—

$$ax^n + bx^{n-1} + \dots + rx + s \dots \quad (2)$$

in which the coefficients a, b, \dots, r, s , are given numbers, positive or negative. Dividing by x^a , we obtain the series—

$$a + \frac{b}{x} + \dots + \frac{r}{x^{n-1}} + \frac{s}{x^n} \dots (2)$$

All the terms of the series (8), after the first, evidently diminish in absolute value as x increases. Suppose the number of those terms to be m , and equate each of them in succession to the quantity $a : m$. Of the resulting values of x , such as

$$\frac{mb}{a} \text{ and } \sqrt{\frac{ms}{a}}$$

let the greatest be denoted by a . Then, if x be made equal to a , the greatest of the terms of (3) after a will be equal to $\frac{a}{m}$; and since the number of those terms is m , their aggregate cannot exceed a numerically, and will be generally less than a . It is evident therefore that if the finite number a be determined as above, the series (3) shall have the same sign as its first term a for all values of x greater than a . And hence it is evident, since

series (2) = series (8) $\times x^n$,

that for all values of x greater than e , the series (2) will assume the sign of the product $a x^n$, which is its own first term. The reasoning applies, and therefore the result holds, whether e be positive or negative; only, in the latter case, by values of x greater than e , we must understand those *numerically greater*. Finally, $f(x)$, of the first number of eq. (1), is of the same form as the series (2); and therefore we can always discover a finite number (e), such, that when that or any greater number, positive or negative, is substituted for (x), the function $f(x)$ will assume a value having the same sign as its first term x^n .

2. Let us apply the preceding results in illustration of the statement, that every algebraic equation has at least one root. We shall suppose in every case, that the given equation has been reduced to the form (1), and that the finite number c , which we have just had under consideration, has been properly determined. When the last term p_n of the equation is equal to 0, there is evidently a root equal to 0; for when 0 is substituted for x , all the terms disappear. Suppos-

ing then that p_n has some finite value, we shall distinguish four cases, depending on the degree of the equation and the sign of p_n . First case: n odd, p_n negative. When $x = 0$, $f(x)$ is negative, because it is reduced then to p_n : when $x = +a$, $f(x)$ assumes the sign of its first term a^n , which is $+$. Now $f(x)$ being a continuous function of x , and passing from negative to positive when x passes from 0 to $+a$, there must be at least one value of x between 0 and $+a$, for which $f(x)$ equals nothing. In this case, therefore, the equation has at least one real positive root. Second case: n odd, p_n positive. When $x = 0$, $f(x)$ is positive: when $x = -a$, $f(x)$ assumes the sign of $(-a)^n$, which is $-$, because n is odd: so that $f(x)$ passes from positive to negative when x passes from 0 to $-a$. And therefore, in this case, the equation has at least one real negative root. Third case: n even, p_n negative. Here $f(x)$ is negative when $x = 0$; positive when $x = +a$; positive also when $x = -a$, because n is even. So that in this case the equation has at least two real roots, one positive, another negative. Fourth and last case: n even, p_n positive. Here $f(x)$ has the same sign $+$ when $x = 0$, when $x = +a$, and when $x = -a$; so that our test fails. And it may be shown, by a simple example or two, that an equation of the form specified in this fourth case may or may not have a real root. The equation

$$x^2 - 7x + 12 = 0$$

has two real roots, 4 and 3, as may be seen by solving the equation, or by substituting 4 and 3 successively for x . The equation

$$x^2 + 12x + 35 = 0$$

has two real roots, -7 and -5 . The equation

$$x^2 + 4 = 0$$

has no real root; for the least value of the first member, for real values of x positive or negative, is positive and equal to 4. It has two imaginary roots, $+\sqrt{-4}$ and $-\sqrt{-4}$, or, as they are usually written, $\pm 2\sqrt{-1}$. The equation

$$x^2 - 8x + 25 = 0$$

has no real root. Solving by the ordinary method, we find the roots to be $4 + \sqrt{-9}$ and $4 - \sqrt{-9}$, or $4 \pm 3\sqrt{-1}$, both imaginary. And accordingly, each of the expressions $4 + 3\sqrt{-1}$ and $4 - 3\sqrt{-1}$, when substituted for x , satisfies the equation. Finally, the equation—

$$x^4 + 2x^2 + 3x^4 + 4x^2 + 6 = 0$$

has no real root; because the least value of the first member, for real values of x positive or negative, is evidently positive and equal to 6. It would be easy to obtain any number of equations, of any even degree, having no real roots. The

question then arises: Must every algebraic equation have some root? Or if the affirmative to this be considered self-evident, another question presents itself, which indeed includes the former: Can we assume any general algebraic expression, or form of magnitude, and assert, that every algebraic equation must have at least one root of that form? To illustrate the question, let us look back to the preceding examples, and assume a and b as general symbols of real number, positive or negative. The first two equations have roots (4, 3, and -7 , -5) of the form a : the third has no root of this form, but two ($\pm 2\sqrt{-1}$) of the form $b\sqrt{-1}$: the fourth has no root of the form a , none of the form $b\sqrt{-1}$, but two ($4 \pm 3\sqrt{-1}$) of the form $a + b\sqrt{-1}$. Of these forms, the first two, a and $b\sqrt{-1}$, are included in the third, $a + b\sqrt{-1}$; for the latter is reduced to a and to $b\sqrt{-1}$ respectively, when $b = 0$, and when $a = 0$; so that each of these four equations has a root, of the form $a + b\sqrt{-1}$. With regard to the fifth equation, which is of the 8th degree, we have seen that it has no root of the form a ; but as yet we can say nothing more. And if an equation, say of the 40th degree, were proposed, having certainly no real root, possibly, as far as we have yet seen, the simplest of its roots would be as complex in relation to $a + b\sqrt{-1}$ as the equation of the 40th degree is itself complex in relation to a quadratic. It is therefore an interesting theorem, as well as a fundamental one, in the Theory of Equations, that every algebraic equation has at least one root of the form $a + b\sqrt{-1}$. It is a very difficult proposition, and remained a long time unproved. Demonstrations of it have been given by Gauss, Cauchy, Ivory, and other eminent mathematicians; but they are all very tedious, and far from elementary. I can only refer the reader to Cauchy's *Cours d'Analyse*, or to Lefebure de Fourcy's *Algebre*, where he will find Cauchy's proof, which is perhaps the best upon the whole that has been published. In what follows, this theorem will be assumed.

8. In the study of the properties of equations, the following algebraical theorem is found to be of the greatest consequence. If the first member of equation (1), or the polynomial

$$x^n + p_1 x^{n-1} + p_2 x^{n-2} + \dots + p_{n-1} x + p_n$$

be divided by $(x - a)$, where (a) is any quantity; and if the division be carried on till the remainder is independent of x ; then, 1st, the remainder is

$$a^n + p_1 a^{n-1} + p_2 a^{n-2} + \dots + p_{n-1} a + p_n;$$

and, 2dly, the quotient is a polynomial

$$x^{n-1} + q_1 x^{n-2} + q_2 x^{n-3} + \dots + q_{n-2} x + q_{n-1};$$

where each of the coefficients (q) is obtained by

EQU

adding the coefficient (p) of the same order (or suffix) to the coefficient (q) of the preceding order, multiplied by (a), that is,

$$q_1 = a + p_1, q_2 = a q_1 + p_2 = a^2 + a p_1 + p_2, \&c.$$

To prove the first part, represent the dividend by $f(x)$, the quotient by $\phi(x)$, the remainder by R : then, by the nature of division,

$$f(x) = (x - a) \phi(x) + R \dots\dots (8)$$

This being an identical equation, holds when $x = a$; but in that case,

$$f(x) = f(a); (x - a) \phi(x) = (a - a) \phi(a) = 0;$$

and R is unchanged, because independent of x . So that, when $x = a$, the equality (8) becomes

$$f(a) = R;$$

and therefore, the remainder may be obtained from the dividend by the substitution of a for x throughout: which was to be proved. The second part of the theorem, or the law of the coefficients $q_1, q_2, \&c.$, is discovered, perhaps most easily, by a little reflection upon the actual process of the division by $x - a$. If the reader is not already familiar with the proposition, he may find an advantage in verifying it upon particular cases, as in dividing

$$x^2 + p x + q \text{ or } x^3 + p x^2 + q x + r \text{ by } x - a.$$

As an immediate deduction from the first part, we obtain the following fundamental theorem:—If (a) be a root of the eq. (1), the first member of the eq. is divisible without remainder by $(x - a)$; and conversely, if the first member be exactly divisible by $(x - a)$, the quantity (a) is a root of the equation. For, if a be a root, $f(a)$ is equal to nothing, so that the division by $x - a$ leaves no remainder; and conversely, if there be no remainder, $f(a)$ is equal to nothing, or a is a root of the equation.

Observing now that the eq. (1) of the n th degree has at least one root, which may be represented by a , we infer from the theorem now proved that

$$f(x) = (x - a) f_1(x),$$

where $f_1(x)$ is a polynomial of the form

$$x^{n-1} + q_1 x^{n-2} + \dots + q_{n-2} x + q_{n-1},$$

a rational integer function of x , of the degree $n - 1$. Again, the equation $f_1(x) = 0$ has at least one root, which may be represented by b . Reasoning then as in the former case, we find

$$f_1(x) = (x - b) f_2(x).$$

Where $f_2(x)$ is a rational integer function of x , its first term equal to x^{n-2} . Substituting this value of $f_1(x)$ in that of $f(x)$ given above, we find

$$f(x) = (x - a) (x - b) f_2(x).$$

In the same manner, assuming c as a root of the

EQU

equation $f_2(x) = 0$, we find

$$f(x) = (x - a) (x - b) (x - c) f_3(x).$$

The process may be continued till we arrive at $f_{n-1}(x)$, which will be evidently of the first degree in x , and its first term equal to x : so that $f_{n-1}(x)$ may be put equal to $x - l$. And hence,

$$f(x) = (x - a) (x - b) \dots (x - k) (x - l):$$

that is: $f(x)$, or the first member of eq. (1), is the continued product of (n) factors of the first degree in x , and each of the form $(x - a)$. This result gives a beautiful view of the structure of algebraic equations, when reduced to the standard form (1). One of the simplest conclusions deducible from it is this: that every equation has as many roots as it has dimensions, and no more. It appears thus: Each of the n quantities, $a, b, c, \dots k, l$, is a root of the equation $f(x) = 0$; for the product $f(x)$ vanishes when any one of the factors $x - a, x - b, \dots x - l$, vanishes, or when $x = a$, when $x = b, \dots$ when $x = l$. No other quantity than these can be a root of the equation; for the product $f(x)$ cannot vanish while each of its factors $x - a, x - b, \dots x - l$, has a value different from zero. The number of the roots of eq. (1) is therefore n . But to prevent wrong notions, observe that in particular cases, any number of the quantities $a, b, \dots l$ may be equal to each other. Suppose that

$$a = b, \text{ and } k = l = 0;$$

then the product $f(x)$, still of the n th degree in x , becomes

$$(x - a)^2 (x - c) \dots (x - k) x^2;$$

and the number of different values of x that satisfy the equation is now not n , but $n - 2$. Cases of this kind are not allowed to stand as exceptions to the general statement: we consider, in the instance now supposed, that the equation $f(x) = 0$ has still n roots, two of them equal to a , and two equal to zero. And in this way it holds universally, that an equation of the n th degree has neither less nor more than n roots.

4. An important property of Imaginary Roots may now be established. The most general form of such a root is $h + k \sqrt{-1}$, where h and k are real, and k different from zero. If this expression be substituted for x in the first member of eq. (1), the result may be represented by $H + K \sqrt{-1}$; where H and K are rational integer functions of h and k independent of $\sqrt{-1}$, H involving only even powers of k , and K involving an odd power of k in each of its terms. K may therefore be divided by k , and if the quotient be represented by L , the above expression becomes

$$H + k L \sqrt{-1} \dots (9)$$

If we had commenced with the substitution of

$k - k\sqrt{-1}$ for x , the resulting value of $f(x)$ would be

$$H - kL\sqrt{-1}; \dots (4)$$

this being the value of $H + kL\sqrt{-1}$ when k is changed into $-k$, because H and L involve only even powers of k . Now, if $k + k\sqrt{-1}$ be a root of the equation $f(x) = 0$, the expression (3) must vanish: and by a first principle of Algebra in relation to imaginary quantities, this condition is equivalent to the two equations

$$\begin{aligned} H &= 0 \text{ and } kL = 0, \text{ or} \\ H &= 0 \text{ and } L = 0: \end{aligned}$$

and if these equations be satisfied, the expression (4) also will vanish. But we have seen that the expressions (3) and (4) are the values of $f(x)$ when the quantities $k + k\sqrt{-1}$ and $k - k\sqrt{-1}$ respectively are substituted for x : and we infer, that the conditions necessary to constitute $k + k\sqrt{-1}$ a root of (1) are sufficient to constitute $k - k\sqrt{-1}$ also a root. In other words: *Imaginary roots occur always in pairs, of the form $(k \pm k\sqrt{-1})$, differing only in the sign of the imaginary part.* Such a pair are called *Conjugate Roots*.

Hence we deduce an interesting result on the composition of $f(x)$. The factors $x - a$, $x - b$, $\dots x - l$, of which we have shown that $f(x)$ is composed, are not real unless the roots a , $b \dots l$ are real. If the equation have a pair of imaginary roots $k \pm k\sqrt{-1}$, the two factors $(x - a)$ of $f(x)$ corresponding to them are

$$\begin{aligned} (x - k) - k\sqrt{-1}, \text{ and} \\ (x - k) + k\sqrt{-1}; \end{aligned}$$

and their product is $(x - k)^2 + k^2$, or $x^2 - 2xk + (k^2 + k^2)$.

And hence: the first member of eq. (1) is composed of as many *real factors* of the 1st degree (of the form $x - a$) as the equation contains real roots, with as many *real factors* of the 2d degree (of the form $x^2 + bx + c$) as the equation contains pairs of imaginary roots.

5. Given the roots of an equation, required the equation itself: more definitely; Given the roots of the eq. (1), required the coefficients $p_1, p_2 \dots p_n$. To solve the question in any case; subtract each root from x , multiply the results together, arrange the product in a series of multiples of powers of x , and equate it to 0: this equation is that required; for (by section 8) it admits of all the assigned roots, and of those only. What we wish to obtain, however, is a general view of the results of this process. To begin with a simple case, let the assigned roots be two, a and b . The equation is

$$\begin{aligned} f(x) &= (x - a)(x - b) = 0, \text{ or} \\ x^2 - (a + b)x + ab &= 0; \end{aligned}$$

and therefore, $-p_1 = a + b$, $p_2 = ab$.

Again, let the assigned roots be a, b, c . The equation is of the form

$$f(x) = x^3 + p_1x^2 + p_2x + p_3 = 0:$$

and if we multiply the trinomial $f(x)$ of the last example by $x - c$, we find

$$\begin{aligned} -p_1 &= a + b + c, \\ p_2 &= ab + ac + bc, \quad -p_3 = abc. \end{aligned}$$

Several cases thus taken are sufficient to suggest the following theorem: In the eq. (1), $-p_1$ = sum of the roots, p_2 = sum of the products of every two, $-p_3$ = sum of the products of every three; and generally, $(-1)^m p_m$ = sum of the products of every m roots. To prove the theorem; assume it to be true for an equation

$$x^{n-1} + q_1x^{n-2} + \dots + q_{n-1} = 0 \dots (2.)$$

Multiplying the first member by $x - l$, and equating to 0, we obtain an equation

$$x^n + (q_1 - l)x^{n-1} + (q_2 - lq_1)x^{n-2} + \dots = 0,$$

or more briefly,

$$x^n + p_1x^{n-1} + p_2x^{n-2} + \dots + p_n = 0 \dots (1.)$$

The roots of eq. (1) are the same as those of eq. (2), with the additional one, l ; and the coefficients of (1) are obtained from l and the coefficients of (2) as follows:—

$$-p_1 = -q_1 + l, \quad (3)$$

$$p_2 = q_2 - lq_1, \quad (4)$$

$$-p_3 = -q_3 + lq_2,$$

and so on, the law being evident, to p_n , which $= -lq_{n-1}$. Now, by the assumption, $-q_1$ is the sum of all the roots of eq. (1) except l ; and therefore, the value of p_1 as determined by the equality (3), is according to the theorem. Again, the sum of the products of every two roots of eq. (1) may be divided into two parts, one containing all the products which do not involve l , the other containing those that do involve l ; and it is evident that by the assumption, q_2 is equal to the first of those parts, and $-lq_1$ equal to the second; so that the value of p_2 determined by the equality (4) is also according to the theorem. Precisely similar reasoning applies to the succeeding coefficients p_3 , &c.; therefore, *if the theorem be true for every equation of the $(n-1)$ th degree, it is also true for every equation of the n th.* But the theorem is verified, as we have seen above, for an equation of the 3d degree; it is therefore true for one of the 4th degree, and so on, from one degree to the next above it; so that it holds for all equations. The proof now given is a good example of *demonstrative induction*, a kind of reasoning often employed in algebraic inquiries.

Examples.—The equation whose roots are 1 and 2 is

$$x^2 - 3x + 2 = 0;$$

that whose roots are $-1, 1, 2$, is

$$x^3 - 2x^2 - x + 2 = 0;$$

that whose roots are $1, -1, \sqrt{-1}, -\sqrt{-1}$, is

$$x^4 - 1 = 0.$$

There is a corollary to this theorem that will be useful to us in what follows. Keeping the same notation as before, we have (by section 8)

$$f(x) = (x-a)(x-b)\dots(x-l).$$

Changing x into $x+h$, we obtain

$$f(x+h) = \{h+(x-a)\}\{h+(x-b)\}\dots\{h+(x-l)\};$$

and if the multiplications indicated in the second member were performed, the result would be a polynomial

$$h^n + Ah^{n-1} + \dots + Qh + R,$$

where the coefficients $A\dots Q, R$, are independent of h . From the definition given in section (1), it is evident that Q is the differential coefficient of $f(x)$; and by the theorem just proved, Q is the sum of all the products of the n quantities $x-a, x-b, \dots, x-l$, taken $n-1$ together, products that may be found by the division of $f(x)$ by each of the quantities $x-a, \dots, x-l$, separately. Hence, the differential coefficient of $f(x)$ is equal to

$$\frac{f(x)}{x-a} + \frac{f(x)}{x-b} + \dots + \frac{f(x)}{x-l}$$

and also, by section (1), equal to

$$nx^{n-1} + (n-1)p_1x^{n-2} + \dots + p_{n-1};$$

so that *these two expressions are equal*; a very useful algebraic theorem.

6. Let us inquire, for a moment, how far we are yet advanced towards the solution of our principal question: To find the roots of an equation. To discover the roots in the most elementary manner, we proceed by trial, substituting particular numbers for x , and retaining those as roots that satisfy the equation. The theorem

$$f(x) = (x-a)(x-b)\dots(x-l),$$

as extended in the end of section (4), suggests another method of proceeding; as it reduces the determination of the roots of $f(x) = 0$ to the decomposition of $f(x)$ into its real factors, simple or quadratic. Obtaining the factors we obtain the roots. But the latter inquiry is of such a nature, that this result must be considered, not as in any proper sense a *solution*, but as a mere *transformation* of the original question into a definite algebraic form. In the same connection, observe, that if we have discovered one root a , or two roots a and b , of $f(x) = 0$, we may divide $f(x)$ by $x-a$, or by the product $(x-a)$

$(x-b)$: the quotient equated to 0, will admit of the remaining roots of the proposed equation, and no more. And generally, if $f(x)$ can be decomposed into the factors P, Q, R , involving x , the roots of $f(x) = 0$ are precisely those of the equations

$$P = 0, Q = 0, R = 0,$$

each of which is of less dimensions than the proposed equation, and on that account more easily solved. For example, the binomial $x^3 - 1$ is divisible by $x - 1$, and the quotient is $x^2 + x + 1$; therefore, the roots of

$$x^3 - 1 = 0 \dots (2)$$

are those of the two equations

$$x - 1 = 0, x^2 + x + 1 = 0.$$

Solving the last, we find the three roots of eq. (2), or the three cube roots of 1, to be

$$1, \frac{-1 + \sqrt{-3}}{2}, \frac{-1 - \sqrt{-3}}{2}.$$

Similarly, or by a change of signs, we find, that the equation $x^3 + 1 = 0$ has the three roots

$$-1, \frac{1 + \sqrt{-3}}{2}, \frac{1 - \sqrt{-3}}{2}$$

In like manner, the equation $y^6 - 1 = 0$, may be transformed into

$$(y^3 - 1)(y^3 + 1) = 0;$$

so that the sixth roots of unity are the roots of the two equations $y^3 - 1 = 0$ and $y^3 + 1 = 0$, already found. In the last section it has been shown, how, when the roots of an equation are given, the coefficients, or the equation itself, is determined. It is natural to suppose, at first sight, that the relations there found to subsist between the coefficients and the roots might be inverted in some simple manner, so as to give the roots in terms of the coefficients; and if this were done, it would furnish a complete resolution of all algebraic equations. But it appears, upon examination, that those relations between the coefficients and the roots are not generally capable of being transformed, by any means, in such a manner as to simplify the question of resolution in the least degree. For example: given the coefficients p, q, r , of the cubic equation

$$x^3 + px^2 + qx + r = 0;$$

required the roots, a, b, c . The relations from which we have to proceed are

$$-p = a + b + c$$

$$q = ab + ac + bc, -r = abc;$$

and we have to find a root in terms of p, q, r . Multiplying the first of these equalities by a^2 , the second by $-a$, and then adding the three, we find

$$-pa^2 - qa - r = a^3, \text{ or } a^3 + pa^2 + qa + r = 0;$$

which is just the given equation; so that the question of resolution has not advanced a step. In a similar manner, and with a similar result, we might insulate the root b , or the root c . The same thing happens generally, by whatever means we insulate one of the roots; and we might be sure that it must happen, for the simple reason that a, b, c , are involved in the same manner, in the equations from which we set out, so that the equations are not changed when a, b, c , are interchanged in any manner. For from this it follows, that whatever process leads to a final equation involving only a , should lead to one involving only b , or to one involving only c , by a simple interchange of the letters a and b , or of a and c , throughout; so that the three final equations, being in fact identical with each other, must suffice separately for the determination of the three roots, and must therefore be identical with the proposed equation. Still, the theorem proved in the last section is a very important one; it leads to some valuable properties of roots, besides giving a perfectly clear statement of the conditions that must be fulfilled by the roots of any proposed equation. It was discovered by Harriott, with whose labours and those of Descartes the systematic theory of equations may be said to have originated.

7. We proceed to the Transformation of Equations. As an illustration of the kind of questions that belong to this part of the theory: *Given an equation $f(x) = 0$; required a second equation $f(y) = 0$, such, that between the roots (y) of the 2d and the roots (x) of the 1st there may be an assigned relation, $y = F(x)$.* If possible, resolve the equation $y = F(x)$, considering x as the unknown. Having found thus $x = \phi(y)$, substitute $\phi(y)$ for x in the equation $f(x) = 0$; and the question is solved. For, by the process, the final equation is $f\{\phi(y)\} = 0$; and, therefore, if a, b, \dots, l , be the roots of $f(x) = 0$, the roots (y) of the final equation must be such that $\phi(y)$ shall have the values a, b, \dots, l . But the two equations

$$\phi(y) = x, \text{ and } y = F(x),$$

express the same relation between x and y , so that if two particular values of x and y satisfy one of the equations, they will satisfy also the other. But

$$\phi(y) = a, = b, = \dots, = l; \text{ and therefore } y = F(a), = F(b) \dots = F(l):$$

as required. When the equation $y = F(x)$ cannot be resolved in relation to x , we must have recourse to higher methods. The following are among the most useful elementary problems in transformation. 1st, *To form an equation whose roots shall be the reciprocals of those of a given equation (1).* Two numbers are called reciprocals if their product = 1. Therefore, in this case the equations $y = F(x)$ and $x = \phi(y)$ become

$$y = \frac{1}{x} \text{ and } x = \frac{1}{y}. \text{ Substitute } \frac{1}{y} \text{ for } x \text{ in eq. (1);}$$

and to reduce the resulting equation to the standard form without changing the roots, multiply it by y^n and divide by p_n . 2d, *To change the signs of all the roots of a given equation.* Substitute $-y$ for x ; and if the first term of the resulting equation be negative, as it will be when the degree of the equation is odd, change the sign of every term. 3d, *To multiply all the roots of a given equation (1) by any number h .* By the question, $y = hx$, or $x = y:h$. Substitute $y:h$ for x in (1), and multiply all the terms by h^n . The required equation is

$$y^n + hp_1 y^{n-1} + h^2 p_2 y^{n-2} + \dots + h^n p_n = 0.$$

4th, *Given an equation in the form (1), with numerical coefficients, some of them irreducible fractions: it is required to transform it into another equation, with whole coefficients, but still of the form (1).* Find the least common multiple k of the denominators of all the coefficients, and, by the last problem, transform the proposed equation into another whose roots are k times greater. It is evident that all the denominators will disappear in the transformation, while the coefficient of the highest power of the unknown is still unity: as required. And it is evident that the multiplier k may be taken less, in most cases, than the least common multiple of the denominators. Contrast the present transformation with the elementary reductions to which equations are often submitted, such as clearing of fractions. The object of those reductions is to simplify the equation with a view to resolution; and this end is gained without any change in the value of the roots. In the present case the object is similar: the equation is simplified by the transformation; and although the roots are changed in value, they are changed in a known and simple manner. The next problem is of the same kind. 5th, *To transform a given equation into another which wants a certain term.* In the given eq. (1) change x into $y + h$: develop the terms $(y + h)^n$, $p_1(y + h)^{n-1}$, &c., by the binomial theorem; and find the equation in the form

$$y^n + q_1 y^{n-1} + \dots + q_n = 0 \dots (2)$$

the coefficients $q_1 \dots q_n$, are rational integer functions of h , independent of y . By equating one of them to zero, we can obtain one or more values of h that will give eq. (2) in the assigned form: and we see thus, that the required transformation can be always effected by diminishing each root of the given equation by a certain quantity h . It is found that the removal of the 2d, 3d, . . . n th terms of eq. (2) require the resolution of equations in h , of the 1st, 2d, . . . $(n-1)$ th degrees. To remove the last term q_n , we have to solve the given equation, as might have been expected. The second term (and this is the most

important case), is easily seen to be removable by the diminution of each root of the proposed equation by a certain number h . For

$$-p_1 = a + b + \dots + l$$

and $-q_1 = (a - h) + (b - h) + \dots (l - h) = -p_1 - nh$; and to make $q_1 = 0$, we have

$$p_1 + nh = 0, \text{ or } h = -\frac{p_1}{n}$$

Example.—The quadratic equation

$$x^2 + px + q = 0,$$

transformed thus, gives the equation

$$y^2 - \frac{1}{2}p^2 + q = 0,$$

which gives the two roots (x) equal to

$$-\frac{1}{2}p \pm \frac{1}{2}\sqrt{p^2 - 4q}.$$

6th, To diminish each of the roots of a given equation by any number h . Here, according to the general method, $y = x - h$, and $x = y + h$; so that the eq. (2) of last problem is that required. But with a view to the resolution of numerical equations, the reader ought to master the following solution: Divide the 1st member $f(x)$ of the given eq. by $x - h$, till the remainder is independent of x : denote the quotient by Q_1 and the remainder by R_1 . Divide similarly Q_1 by $x - h$, and let the quotient be Q_2 , and the remainder R_2 : and proceed in this manner to Q_n and R_n . As the divisor is always $x - h$, and the first dividend is $x^n + \&c.$; the first terms of $Q_1, Q_2, \&c.$, must be $x^{n-1}, x^{n-2}, \&c.$; so that $Q_n = 1$. Hence, putting $x - h = y$, we have, by the nature of the process,

$$f(x) = Q_1 y + R_1$$

$$Q_1 = Q_2 y + R_2$$

$$Q_2 = Q_3 y + R_3$$

$$\dots \dots \dots$$

$$Q_{n-2} = Q_{n-1} y + R_{n-1}$$

$$Q_{n-1} = y + R_n$$

Multiply these equations in order, beginning with the second, by $y, y^2, y^3 \dots y^{n-1}$; take their sum, and reject the terms $Q_1 y, Q_2 y^2, \&c.$, common to both members: then

$$f(x) = y^n + R_n y^{n-1} + R_{n-1} y^{n-2} + \dots + R_2 y + R_1.$$

This is an identical equation, y standing for $x - h$; and therefore, if $a, b, \dots l$ be the roots of the given equation, the second member of the last equality will vanish when $x = a, = b, \dots = l$; that is when $y (= x - h) = a - h, = b - h, \dots = l - h$. And therefore the equation

$$y^n + R_n y^{n-1} + R_{n-1} y^{n-2} + \dots + R_1 = 0$$

is that required, its roots (y) being severally less by h than those of the given equation $f(x) = 0$.

8. We proceed now to another kind of transformation, the depression of an equation, or the dimi-

nution of its degree, when some of its roots have particular relations to each other. Upon this subject there are two partial theories of special importance, that of equal roots and that of reciprocal equations: and these we shall take up in order. Let $f(x) = 0$ be any given equation; let $a_1, a_2, a_3 \dots a_n$, be its roots; let $f_1(x)$ be the diff. coeff. of $f(x)$; then, by sections (3) and (5), we have

$$f(x) = (x - a_1)(x - a_2) \dots (x - a_n) \dots (2)$$

$$f_1(x) = \frac{f(x)}{x - a_1} + \frac{f(x)}{x - a_2} + \dots + \frac{f(x)}{x - a_n}.$$

$$\text{Let } \frac{f(x)}{x - a_1} = Q_1, \dots \frac{f(x)}{x - a_n} = Q_n:$$

$$\therefore f_1(x) = Q_1 + Q_2 + \dots + Q_n \dots (3)$$

It should be carefully remembered that each of the terms (Q) of equation (3) is composed of all the factors $(x - a)$ of equation (2), one excepted. Supposing now that the equation $f(x) = 0$ has m roots each equal to a_1 ; it is evident that Q_1 contains $(x - a_1)^{m-1}$ as a factor, and that each of $Q_2, Q_3, \dots Q_n$, contains either $(x - a_1)^{m-1}$ or $(x - a_1)^m$ as a factor; whence, by equation (3), $f_1(x)$ contains $(x - a_1)^{m-1}$ as a factor. We infer, that if the eq. $f(x) = 0$ has m roots equal to a_1 , the two quantities $f(x)$ and $f_1(x)$ have a common factor $(x - a_1)^{m-1}$. Suppose conversely that $f(x)$ and $f_1(x)$ have the common factor $(x - a_1)^{m-1}$. Conceive the terms (Q) of equation (3) distributed into two sets, those of the first set being derived from $f(x)$ by the removal of the factor $(x - a_1)$, and those of the second by the removal of any factor different from $(x - a_1)$: and represent the sum of the first set by B , and that of the second by C . Then

$$f_1(x) = B + C, \text{ or, } B = f_1(x) - C.$$

Now, by hypothesis, $(x - a_1)^{m-1}$ is a factor of $f_1(x)$; it is also, by our assumption, a factor of C , and therefore a factor of the difference $f_1(x) - C$, and therefore, by the last equation, a factor of B : in other words, $(x - a_1)^{m-1}$ is a factor of the aggregate of those terms (Q) which we derive from $f(x)$ by throwing out the factor $(x - a_1)$. It follows evidently, that $f(x)$ contains the factor $(x - a_1)^m$. And hence, if $f(x)$ and $f_1(x)$ have a common factor $(x - a_1)^{m-1}$, the equation $f(x) = 0$ has m roots each equal to a_1 . By a simple extension of this reasoning: if the equation $f(x) = 0$ has m roots equal to a , p roots equal to b , q roots equal to c , then, $f(x)$ and $f_1(x)$ have a common divisor—

$$(x - a)^{m-1} (x - b)^{p-1} (x - c)^{q-1};$$

and conversely. Hence, $f(x) = 0$ being the given equation, and (d) being the greatest common measure of $f(x)$ and $f_1(x)$: if (d) be numerical, or independent of (x) the equation has no

EQU

equal roots: if d contain any number of simple factors $(x - a)$, the equation has the same number of double roots (a) : if d contain any number of double factors $(x - b)^2$, the equation has the same number of triple roots, &c. To simplify now the resolution of equations which have equal roots. Denote by u the product of those factors $(x - a)$ of $f(x)$, which correspond to the simple roots; by v the product of the factors, taken in the first degree, which correspond to the double roots; by w the product of the factors, also in the first degree, corresponding to the triple roots: and suppose that there are no roots of a higher degree of multiplicity. Then

$$f(x) = u v^2 w^3;$$

and d being, as above, the G. C. M. of $f(x)$ and its diff. coeff. $f_1(x)$; we have, by the theorem,

$$d = v w^2.$$

In like manner, if e be the G. C. M. of d and the diff. coeff. of d , we find, by the theorem,

$$e = w.$$

Dividing each of these equations by the succeeding;

$$f(x) \cdot d = u v w, d : e = v w, e = w.$$

Dividing each of these by the succeeding;

$$\frac{f(x) \cdot e}{d^2} = u, \frac{d}{e^2} = v, e = w.$$

Now, when $f(x)$ is given in the form (1), with numerical coefficients, we can find $f_1(x)$ by the rule in section (1), and then d by the process of G. C. M., and then e in like manner; so that we can find u, v, w , in terms of x . In this way we reduce the resolution of the proposed equation to that of the three equations $u = 0, v = 0, w = 0$, none of which has equal roots, and of which the degree, taken altogether, are less than that of the proposed. And a similar method applies to more complex cases.

For example, given the equation

$$x^7 - x^6 - 4x^5 + 4x^4 + 5x^3 - 5x^2 - 2x + 2 = 0;$$

we find successively,

$$f_1(x) = 7x^6 - 6x^5 - 20x^4 + 16x^3 + 15x^2 - 10x - 2;$$

$$d = x^3 - x^2 - x + 1; e = x - 1.$$

By divisions, as indicated above, we find

$$f(x) : d = u v w = x^4 - 8x^3 + 2;$$

$$d : e = v w = x^2 - 1; e = w = x - 1.$$

And by division again,

$$u = x^2 - 2, v = x + 1, w = x - 1.$$

The question is reduced to the resolution of the three equations

$$x^2 - 2 = 0, x + 1 = 0, x - 1 = 0.$$

EQU

The given equation has two simple roots $\pm \sqrt{2}$, a double root -1 , and a triple root $+1$: or

$$f(x) = (x^2 - 2)(x + 1)^2(x - 1)^3.$$

9. An equation is called reciprocal when it is such, that if a be any one of its roots, $\frac{1}{a}$ is also a root; so that all the roots will be reproduced, though in a different order, by the division of unity by each of them. Given an equation in the form (1); by what characters may we know that it is a reciprocal equation? Substituting $\frac{1}{x}$ for x in eq. (1), and reducing, we obtain the equation

$$x^n + \frac{p_{n-1}}{p^n} x^{n-1} + \frac{p_{n-2}}{p^n} x^{n-2} + \dots + \frac{p_1}{p^n} x + \frac{1}{p^n} = 0 \dots (2.)$$

The roots of eq. (2) are the reciprocals of those of those of (1). It follows, that if (1) be a reciprocal equation, (1) and (2) have the same roots, and are therefore identical with each other: and conversely. But we can identify (1) and (2) only by equating their coefficients in order. Therefore

$$\frac{p_{n-1}}{p^n} = p_1, \frac{p_{n-2}}{p^n} = p_2 \dots \frac{p_1}{p^n} = p_{n-1},$$

$$\frac{1}{p^n} = p_n.$$

From the last equality we find $p_n^2 = 1$: therefore

$$p_n = \pm 1, p_{n-1} = \pm p_1, p_{n-2} = \pm p_2, \&c.$$

One or other of these two sets of relations among the coefficients is necessary and sufficient to constitute (1) a reciprocal equation. Observe, however, that if n be even, and p be the coefficient of the middle term, we find as above, $p = \pm p$; and therefore, in the case of the upper sign, p may have any value, but in the case of the lower, p must vanish. Hence, in a reciprocal equation, the coefficients of terms equidistant from the extremes must be equal and of like signs, or equal and of unlike signs: also, when the equation is of even dimensions, and the corresponding terms have unlike signs, there must be no middle term. On the resolution of such equations, observe, first, that all cases may be reduced to that of a reciprocal equation of an even degree, with its last term positive. Consider the equations

$$x^5 + a x^4 + b x^3 + b x^2 + a x + 1 = 0,$$

$$x^5 + a x^4 + b x^3 - b x^2 - a x - 1 = 0.$$

It appears by substitution, that -1 is a root of the first, and $+1$ of the second: therefore the first members are divisible respectively by $x + 1$ and $x - 1$. Now it is evident, that in the first

EQU

of those quotients, we should have obtained the same coefficients in the same order if we had taken the terms of divisor and dividend in the reverse order ($1 + x, 1 + ax + \&c.$); and likewise in the second quotient, if we had reversed the order and changed all the signs. Hence, the resulting equations of the fourth degree are still reciprocal, and their last terms are $+1$. The same reasoning applies to a reciprocal equation of whatever odd degree: and it appears, in like manner, that when the equation is of even dimensions, and its last term is -1 , it may be depressed, by the removal of the factor $x^2 - 1$, into a reciprocal equation whose last term is $+1$. And therefore, by changing n into $2n$ in eq. (1), and introducing the proper conditions, $p_{2n} = 1, p_{2n-1} = p_1, \&c.$, we shall obtain a general form of reciprocal equation, whose solution will suffice for all cases. Consider then the equation

$$x^{2n} + p_1 x^{2n-1} + p_2 x^{2n-2} + \dots + p_2 x^2 + p_1 x + 1 = 0.$$

Connect by pairs the terms equidistant from the extremes, and divide the equation by x^n : it then becomes

$$\left(x^n + \frac{1}{x^n}\right) + p_1 \left(x^{n-1} + \frac{1}{x^{n-1}}\right) + \dots + p_{n-1} \left(x + \frac{1}{x}\right) + p_n = 0 \dots (2.)$$

Let $x + \frac{1}{x} = z$, and $x^n + \frac{1}{x^n} = R_n$

Multiplying together the two equations

$$R_{n-1} = x^{n-1} + \frac{1}{x^{n-1}}, \text{ and}$$

$$z = x + \frac{1}{x}; \text{ we find}$$

$$\begin{aligned} z R_{n-1} &= \left(x^n + \frac{1}{x^n}\right) + \left(x^{n-2} + \frac{1}{x^{n-2}}\right) \\ &= R_n + R_{n-2} \\ \therefore R_n &= z R_{n-1} - R_{n-2}. \end{aligned}$$

This relation gives the value of each quantity R_n or $x^n + \frac{1}{x^n}$, in terms of z , when the values of the preceding two are known. Thus, $R_1 = z$,

$$R_2 = x^2 + \frac{1}{x^2} = \left(x + \frac{1}{x}\right)^2 - 2 = z^2 - 2.$$

$$R_3 = z R_2 - R_1 = z(z^2 - 2) - z = z^3 - 3z.$$

$$R_4 = z^4 - 4z^2 + 2.$$

$$R_5 = z^5 - 5z^3 + 5z, \&c.$$

Substituting in eq. (2) the values of R_1, R_2, \dots, R_n , in terms of z , we reduce the proposed equation of the $2n$ th degree in x to one of the n th degree in z . Finally,

EQU

$$x + \frac{1}{x} = z, \text{ or } x^2 - zx + 1 = 0$$

$$\therefore x = \frac{z}{2} \pm \frac{1}{2} \sqrt{z^2 - 4};$$

and we have only to substitute in this expression the n values of z , in order to find the $2n$ values of x . As an example, consider the equation

$$x^5 - 1 = 0.$$

When the factor $(x - 1)$, corresponding to the root 1 is removed, the equation becomes

$$x^4 + x^3 + x^2 + x + 1 = 0; \text{ or}$$

$$\left(x^2 + \frac{1}{x^2}\right) + \left(x + \frac{1}{x}\right) + 1 = 0; \text{ or}$$

$$(z^2 - 2) + z + 1 = z^2 + z - 1 = 0.$$

$$\therefore z = \frac{-1 \pm \sqrt{5}}{2}$$

$$\therefore z^2 = \frac{6 \pm 2\sqrt{5}}{4}; \text{ and } z^2 - 4 = \frac{10 \pm 2\sqrt{5}}{4}$$

$$\therefore \sqrt{z^2 - 4} = \frac{1}{2} \sqrt{10 \pm 2\sqrt{5}} : \sqrt{-1}$$

Substituting successively these two values of $\sqrt{z^2 - 4}$, with the corresponding values of z in the expression

$$\frac{z}{2} \pm \frac{1}{2} \sqrt{z^2 - 4},$$

which is the value of x in terms of z , we find that the five roots of the proposed equation, or the five 5th roots of unity are, 1,

$$\frac{-1 + \sqrt{5}}{4} \pm \frac{\sqrt{10 + 2\sqrt{5}}}{4} \sqrt{-1},$$

$$\frac{-1 - \sqrt{5}}{4} \pm \frac{\sqrt{10 - 2\sqrt{5}}}{4} \sqrt{-1}$$

10. The theory of Elimination, or of the resolution of equations which involve more than one unknown, must be noticed here, however, briefly, as it is one of the most important subjects in algebra. The reader, we suppose, has met with examples of simultaneous equations, and with the methods of elimination by addition, by comparison, and by substitution, as applied to equations of the first degree. There is another method, that of Indeterminate Multipliers, which is not usually consigned to the elements, although simple in principle, and very extensively used. Required x and y from the two simultaneous equations

$$\begin{cases} a_1 x + b_1 y = c_1 \\ a_2 x + b_2 y = c_2 \end{cases} \quad (2.)$$

Multiply the second equation by the quantity m , and then add to the first:

EQU

∴ $(a_1 + ma_2)x + (b_1 + mb_2)y = c_1 + mc_2$; (8)
and to eliminate y , assume in eq. (8)

$$b_1 + mb_2 = 0, \text{ or } m = -\frac{b_1}{b_2};$$

$$\therefore \left(a_1 - \frac{a_2 b_1}{b_2}\right)x = c_1 - \frac{b_1 c_2}{b_2};$$

$$\therefore (a_1 b_2 - a_2 b_1)x = b_2 c_1 - b_1 c_2.$$

Proceeding in the same manner, or by substitution, to determine y , we find

$$x = \frac{b_2 c_1 - b_1 c_2}{a_1 b_2 - a_2 b_1}; y = \frac{a_2 c_1 - a_1 c_2}{a_1 b_2 - a_2 b_1}. \quad (4.)$$

The process depends upon this, that the eq. (8) must admit of the solution common to the given equations, whatever be the value of m . As a second question: Required the values of x and y that satisfy the three equations

$$\left. \begin{aligned} a_1 x + b_1 y &= c_1 \\ a_2 x + b_2 y &= c_2 \\ a_3 x + b_3 y &= c_3 \end{aligned} \right\} \quad (5.)$$

From the first and second equations find, as in the last question, the values of x and y , and from the first and third find two other values: then, if the latter values of x and y are equal to the former, the third equation is superfluous, and if unequal, the three given equations are inconsistent. More simply, to make the given equations consistent with each other, substitute the values (4) of x and y in the 3d of equations (5). This gives the equation of condition

$$a_3(b_2 c_1 - b_1 c_2) + b_3(a_2 c_1 - a_1 c_2) = c_3(a_1 b_2 - a_2 b_1).$$

Similar principles apply to higher questions, whenever the number of equations, independent of each other, exceeds the number of unknowns. As a third question: Required the values of x, y, z , that satisfy the three equations

$$\left. \begin{aligned} a_1 x + b_1 y + c_1 z &= k_1, \\ a_2 x + b_2 y + c_2 z &= k_2, \\ a_3 x + b_3 y + c_3 z &= k_3. \end{aligned} \right\}$$

Multiply the second equation by m and the third by n , and add the products to the first. In the resulting equation equate the coefficients of y and of z to 0. This process gives the three equations

$$\left. \begin{aligned} b_1 + mb_2 + nb_3 &= 0 \\ c_1 + mc_2 + nc_3 &= 0 \end{aligned} \right\} \quad (6.)$$

$$(a_1 + ma_2 + na_3)x = k_1 + mk_2 + nk_3. \quad (7.)$$

The equations (6), solved as in the first question, give

$$m = \frac{b_3 c_1 - b_1 c_3}{b_2 c_3 - b_3 c_2} = \frac{M}{D};$$

$$n = \frac{b_1 c_2 - b_2 c_1}{b_2 c_3 - b_3 c_2} = \frac{N}{D}.$$

EQU

Substituting these values of m and n in eq. (7) we find

$$x = \frac{k_1 D + k_2 M + k_3 N}{a_1 D + a_2 M + a_3 N}.$$

From this expression we obtain x in terms of the given coefficients, by substituting for D, M, N , their values $b_2 c_3 - b_3 c_2$, &c.: and from the value of x written at length, that of y may be found by an interchange of the letters a and b without change of suffixes, and that of z from that of x by an interchange of a and c .

11. A complete equation of the n th degree, in x and y , after suitable reductions, may always be written thus:

$$Ax^n + Bx^{n-1} + Cx^{n-2} + \dots + Kx + L = 0;$$

where the coefficients $A, B, C \dots L$, are of the forms,

$$\left. \begin{aligned} a, b + cy, d + ey + fy^2 \dots \\ g + hy + ky^2 + \dots + py^n. \end{aligned} \right\}$$

Given two such equations, one of the n th degree, another of the m th: required all the systems of values which, when substituted for x and y shall satisfy the two equations. The equations may be represented, for brevity, as

$$f(x, y) = 0, \quad \phi(x, y) = 0.$$

If we restrict ourselves to questions having a finite number of solutions, it is evident that $f(x, y)$ and $\phi(x, y)$ can have no common factor involving x or y , or both x and y . Excluding these cases, there is a simple test by which we can discover suitable values of either unknown. Suppose b to be a suitable value of y . Then, by the question the two equations

$$f(x, b) = 0 \text{ and } \phi(x, b) = 0,$$

must have one or more roots in common: and therefore, the polynomials $f(x, b)$ and $\phi(x, b)$ must have a common divisor, $F(x)$, involving x ; and the roots of the equation $F(x) = 0$ are the values of x corresponding to the value b of y . Suppose conversely that $f(x, b)$ and $\phi(x, b)$ have a common divisor $F(x)$: then any root a of the eq. $F(x) = 0$, when substituted for x , will satisfy the two equations $f(x, b) = 0$ and $\phi(x, b) = 0$; and therefore the values a and b of x and y form a solution of the given equations. Upon these principles is founded the method of elimination by the process of greatest common measure. Arrange the polynomials $f(x, y)$ and $\phi(x, y)$ with respect to x , and apply to them the process of G. C. M. till a remainder is obtained involving only y . Let $F(x, y)$ be the last divisor, and $\psi(y)$ the remainder: then if

$$\psi(y) = 0, \quad (8.)$$

the given polynomials have a common measure $F(x, y)$. Therefore the roots of (8) are, according to what precedes, suitable values of y ; and

if any one of them, b , be substituted in the eq. $F(x, y) = 0$ for y , it will give corresponding value of x . Such is the principle of the method; but in practice, this theoretical simplicity disappears, except in rare cases; the principal difficulty arising from the introduction of factors involving y , which give values foreign to the question. The necessary details are given in the most of the good elementary works, such as Bourdon's *Algebra*, *Lefebvre de Fourcy's*. There are other elementary points connected with this subject (such as the extension of the method of indeterminate multipliers to equations of the 2d and higher degrees), which are of great interest, but must be passed for want of space. There is an interesting and precise discussion of the elements of this subject in Peacock's *Algebra*. The object of every method of elimination is, as in the above process, to obtain a *final equation* $\psi(y) = 0$ whose roots are the values of one of the unknowns proper to the question. And a method of elimination is considered *perfect* when it leads to a final equation that admits of all the values of y proper to the question, and of no others. The most general method of this kind is that depending on the properties of *symmetrical functions*.

12. A function of the roots of an equation is called *symmetrical*, when the roots are all involved in it in precisely the same manner, so that the function is not changed when the roots are interchanged for each other in whatever order we please. A function called *symmetrical* is usually understood to be *rational*, or such, that none of the roots is involved in it under a radical sign. It will be remembered that each coefficient of equation (1) is a rational symmetrical function of the roots. According to Newton's method, the first question upon this subject is, to find the sum (s_1) of the first powers of the roots, the sum (s_2) of their second powers, the sum (s_3) of their third powers, &c., in terms of the coefficients of the equation. Newton effected this in a simple and elegant manner by means of the theorem which has been proved in the end of section (5). By actual division, or by the statement made in section (8), we find

$$\frac{f(x)}{x-a} = x^{n-1} + (a+p_1)x^{n-2} + (a^2+p_1a+p_2)x^{n-3} + \dots$$

Substituting successively b, c, \dots, l , for a , in this expression, and adding all the equations together, we find

$$\frac{f(x)}{x-a} + \frac{f(x)}{x-b} + \dots + \frac{f(x)}{x-l} = nx^{n-1} + (s_1 + np_1)x^{n-2} + (s_2 + p_1s_1 + np_2)x^{n-3} + \dots$$

To identify the second member of this equation with the expression

$nx^{n-1} + (n-1)p_1x^{n-2} + (n-2)p_2x^{n-3} + \dots$ which we know, by section (5), to be identical with it, we equate the coefficients of like powers of x . Therefore

$$\begin{aligned} s_1 + np_1 &= (n-1)p_1, \\ s_2 + p_1s_1 + np_2 &= (n-2)p_2, \\ &\dots, \text{ or} \\ (1.) \quad \begin{cases} s_1 + p_1 = 0, \\ s_2 + p_1s_1 + 2p_2 = 0, \\ s_3 + p_1s_2 + p_2s_1 + 3p_3 = 0, \\ \dots \\ s_{n-1} + p_1s_{n-2} + \dots + p_{n-2}s_1 + (n-1)p_{n-1} = 0. \end{cases} \end{aligned}$$

The first of these equations gives s_1 , the second s_2 , the third s_3 , &c.; the highest sum determined thus far being s_{n-1} . Thus,

$$\begin{aligned} s_1 &= -p_1, \quad s_2 = p_1^2 - 2p_2, \\ s_3 &= -p_1^3 + 3p_1p_2 - 3p_3, \\ s_4 &= p_1^4 - 4p_1^2p_2 + 4p_1p_3 + 2p_2^2 - 4p_4; \text{ &c.} \end{aligned}$$

To find the sums of similar powers of the roots whose indices exceed $n-1$, we proceed thus. The given equation, multiplied by x^m , is

$$x^n + p_1x^{n-1} + \dots + p_{n-1}x + p_n = 0.$$

Substituting successively for x each of the roots a, b, \dots, l , and adding the resulting equations together, we find,

$$s_{n+m} + p_1s_{n+m-1} + \dots + p_{n-1}s_{m+1} + p_ns_m = 0.$$

Giving here to m the values 0, 1, 2, 3, &c., and observing that $s_0 = n$, we find the following relations:

$$(2.) \quad \begin{cases} s_n + p_1s_{n-1} + \dots + p_{n-1}s_1 + np^n = 0, \\ s_{n+1} + p_1s_n + \dots + p_{n-1}s_2 + p_ns_1 = 0, \\ s_{n+2} + p_1s_{n+1} + \dots + p_{n-1}s_3 + p_ns_2 = 0; \\ \text{&c.} \end{cases}$$

The sums s_1, s_2, \dots, s_{n-1} , are already known by equations (1); the sum s_n is therefore known by the first of equations (2), the sum s_{n+1} by the second; &c. We can find in the same manner the sums of similar powers of the roots, with negative exponents, by making m equal to $-1, -2$, &c.: but we find these values more easily

by changing x into $\frac{1}{x}$ in the proposed equation,

and then calculating, as above, the sums of similar powers, with positive exponents, of the roots of the transformed equation. The following inferences are obvious:—The expressions of the sums s_1, s_2, \dots in terms of p_1, p_2, \dots will not contain any denominator. If the coefficients (p) are integers, the sums (s) will be also integers. If n sums of similar powers are given, such as $s_1,$

s_1, \dots, s_n , we can determine all the coefficients (p) of the equation by means of (1) and (2).

The next question is to find the value of any double function, or of the sum of all possible terms ($a^\mu b^\nu$), where a is any one root and b any other root; the numbers μ, ν , being integers. Such a function is represented by $\Sigma (a^\mu b^\nu)$, Σ standing for "sum of;" thus, $p_2 = \Sigma (a b)$. According to the previous notation, we have

$$s_\mu = a^\mu + b^\mu + \dots + l^\mu;$$

$$s_\nu = a^\nu + b^\nu + \dots + l^\nu.$$

The product of the second members consists of two parts; first, the sum of all possible terms of the form $a^\mu + b^\nu$; second, the sum of all possible terms of the form $a^\mu b^\nu$. Therefore

$$s_\mu \cdot s_\nu = s_{\mu+\nu} + \Sigma (a^\mu b^\nu); \text{ or}$$

$$\Sigma (a^\mu b^\nu) = s_\mu s_\nu - s_{\mu+\nu}$$

And hence, any double function whatever may be expressed, under a rational and integer form, by the coefficients (p) of the given equation. The last formula is altered if $\mu = \nu$; for then $a^\mu b^\nu = a^\nu b^\mu$, so that the terms of the double function become equal, by pairs, and the function is reduced to $2 \Sigma (a^\mu b^\mu)$. Therefore

$$\Sigma (a^\mu b^\mu) = \frac{1}{2} \{ (s_\mu)^2 - s_{2\mu} \}$$

The denominator 2 disappears when we substitute for s_μ and $s_{2\mu}$. Having found the values of all simple and double functions of the roots in terms of the coefficients (p), we have to find next the value of any triple function $\Sigma (a^\lambda b^\mu c^\nu)$; and this we do by multiplying together the double function $\Sigma (a^\lambda b^\mu)$ and the simple function s_ν , and then proceeding in the same manner as above. Without having the work placed before him, the reader will easily find the value of the triple function, in terms of simple functions, and in its simplest form, to be

$$s_\lambda s_\mu s_\nu - s_\lambda s_{\mu+\nu} - s_\mu s_{\lambda+\nu} - s_\nu s_{\lambda+\mu} + 2 s_{\lambda+\mu+\nu}$$

And the same method applies to the determination of quadruple functions, and of the successive symmetrical functions of higher orders. Each of the symmetrical functions yet considered is homogeneous, or such, that the exponents of the letters are the same in all its terms. But it is easily seen that a rational symmetrical function which is not homogeneous must be the sum of two or more such functions which are homogeneous; and further, that every non-integer symmetrical function may be reduced to a quotient of one integer symmetrical function by another. Hence, the expression of any rational symmetrical function whatever, in terms of the coefficients, may be derived by mere addition and division from the expressions of the simple, double, triple . . . functions above investigated. From all which it follows that, by Newton's

method, every rational symmetrical function of the roots of an equation is expressible rationally by the coefficients of the equation. The properties of symmetrical functions are of the greatest importance in the theory of equations. They have therefore been studied with great diligence by several eminent algebraists, particularly Waring, Lagrange, and Cauchy; whose inquiries have led to some very remarkable methods and results. But to these matters want of space prevents further reference.

18. We have already discussed a few simple problems in the transformation of equations. Upon the same subject there are several important questions, of a higher kind, which are cases of the following:—Given an equation; required any assigned rational function of two or more of its roots. In the investigation of such questions it is generally found, that symmetrical functions of the roots of the given equation present themselves naturally, and as the principal elements of the solution. One example will be given here, which is of great interest historically and upon other accounts. To find an equation whose roots shall be the squares of the differences of the roots of a given eq. (1.) The n roots of eq. (1) being a, b, \dots, l ; those of the required equation are $(a-b)^2, (a-c)^2, (b-c)^2$, &c.; and their number is the number of combinations (not permutations) of n letters taken two together, and therefore equal to $\frac{n(n-1)}{2} = \mu$. The re-

quired equation is therefore of degree μ , and may be represented by

$$x^\mu + q_1 x^{\mu-1} + q_2 x^{\mu-2} + \dots + q_\mu = 0. (2.)$$

The question is to find the coefficients (q), which are evidently symmetrical functions of the roots of eq. (1). The following process is due to Lagrange. As in the last section, let s_1, s_2, \dots be the sums of similar powers of the roots of eq. (1); let S_1, S_2, \dots be the like functions of the roots of eq. (2); and let

$$\phi(x) = (x-a)^{2m} + (x-b)^{2m} + \dots + (x-l)^{2m}.$$

By substitution of a, b, \dots, l , successively for x in the last equation, and by addition of the results, it is easily found that

$$\phi(a) + \phi(b) + \phi(c) + \dots + \phi(l) = 2 S_\mu.$$

Developing now the different terms $(x-a)^{2m}$, &c., of $\phi(x)$, by the binomial theorem, we find that $\phi(x) =$

$$x^{2m} - 2m a x^{2m-1} + \dots + a^{2m}$$

$$+ \dots$$

$$+ x^{2m} - 2m l x^{2m-1} + \dots + l^{2m};$$

where the reader, if he finds it necessary, may supply a few additional terms. Adding the n polynomials contained in the second member of the last equation, we find

EQU

$$\phi(x) = nx^{2m} - 2ms_1x^{2m-1} + \dots + s_{2m}.$$

Substituting successively $a, b, \dots l$ for x in this equation, and adding the resulting equations, we obtain the following value of $\varphi(a) + \varphi(b) + \dots + \varphi(l)$, or of $2 S_m$;

$$n s_{2m} - 2m s_1 s_{2m-1} + \frac{2m(2m-1)}{1 \cdot 2} s_2 s_{2m-2} - \dots + n s_{2m}.$$

It is easily seen that in this expression the terms equidistant from the extremes are equal. Connecting equal terms, and dividing by 2, we find

$$S_m = n s_{2m} - 2ms_1 s_{2m-1} + \frac{2m(2m-1)}{1 \cdot 2} s_2 s_{2m-2} - \dots$$

$$\pm \frac{1}{2} \frac{2m(2m-1) \dots (m+1)}{1 \cdot 2 \cdot 3 \dots m} s_m s_m.$$

To find now the coefficients (q) in terms of the coefficients (p) of eq. (1):

1st. Calculate the sums $s_1, s_2, \dots, s_n, \dots, s_{2m}$, in terms of the coefficients (p) , by Newton's formulas.

2d. Calculate the sums S_1, S_2, \dots, S_μ , in terms of (p) , by the formula last obtained. Thus, making $m = 1, = 2$; $S_1 = n s_2 - s_1 s_1$, $S_2 = n s_4 - 4 s_1 s_3 + 8 s_2 s_2$, &c.

3d. Calculate the coefficients (q) in terms of (p) by Newton's formulas, $q_1 + S_1 = 0$, &c. These operations are extremely prolix, when n is greater than 2 or 3. There is another very interesting question, of the same class with that now solved: Required an equation whose roots shall be equal to $a + b + k a b$, where a is any root of a given eq. (1), b any other root of (1), and k any given number. By a simple course of reasoning, in connection with this question, Lagrange has proved, that when the equation $f(x) = 0$ is of even dimensions, $f(x)$ is decomposable into real quadratic factors; seeming to prove thus the fundamental theorem which we have assumed, that every equation has at least one root real or imaginary. Lagrange's investigation, considered as establishing this last result, is certainly open to objection: it is not perfectly clear that the thing to be proved is not virtually assumed in the proof, the laws of the composition and transformation of equations being assumed throughout. Dr. Peacock has obviated this objection by presenting the proof in another form, which, though not in all respects quite satisfactory, is certainly rigorous, and well worthy of attention. Lagrange's proof may be found in the appendix to Bourdon's *Algebre*; the other in a paper by Dr. Peacock, contained in the *Reports of the British Association* for 1838, where there is much valuable information to be had upon the theory of equations and other branches of analysis.

14. The properties of symmetrical functions find their most useful application in the follow-

EQU

ing method of elimination. Let

$$x^m + p_1 x^{m-1} + \dots + p_{m-1} x + p_m = 0 \quad (1.)$$

$$x^n + q_1 x^{n-1} + \dots + q_{n-1} x + q_n = 0 \quad (2.)$$

be two equations in x and y , of degrees m and n . The coefficients p and q are all rational integer functions of y ; and their dimensions are equal to their suffixes, if the equations are complete. Let a, b, c, \dots, l be the m roots (x) of eq. (1.) Substituting these in eq. (2), we find the m results

$$(4.) \begin{cases} a^n + q_1 a^{n-1} + \dots + q_{n-1} a + q_n, \\ b^n + q_1 b^{n-1} + \dots + q_{n-1} b + q_n, \\ \vdots \\ l^n + q_1 l^{n-1} + \dots + q_{n-1} l + q_n. \end{cases}$$

Let V be the product of these polynomials; then

$$\mathbf{V} = 0 \quad (b.)$$

is the final equation resulting from the elimination of x between the equations (1) and (2); for it is satisfied by every value of y that makes any of the quantities (4) vanish, and by no others. Now, V is evidently a symmetrical function of the roots of (1); for when a, b, c, \dots, l , are interchanged in any manner for each other, the only effect upon V is a change in the order of its factors. And hence, without obtaining the expressions (4) by the resolution of eq. (1), which is often impossible, we can express the product V in terms of the coefficients (p) and (q) by processes of which the elements have been already indicated (sect. 11); and the question is then reduced to the resolution of the final equation, which involves only y . The method is open to one objection, that the operations required by it are in most cases very prolix. On the other hand, it gives a final equation, which admits of all the roots, and those only that are proper to the question. It leads also, in a simple manner, to the theorem of Bezout, which is, *that the degree of the final equation is at most equal to the product of the degrees of the given equations.* The proof may be indicated briefly, for the case of two equations. Retaining the above notation, each term of the polynomial V is the product of m terms taken separately from the m polynomials (4), and may therefore be represented by

$$q_n - a \ q_n - \beta \dots q_n - \lambda \cdot a^{\alpha} b^{\beta} \dots \lambda.$$

As V is symmetrical in relation to $\alpha, \beta, \dots, \lambda$ it must contain all the terms of this form obtainable by interchange of the constant indices $\alpha, \beta, \dots, \lambda$, for each other; the sum of which terms is

$$q_n - \alpha q_n - \beta \dots q_n - \lambda \sum \alpha^s b^s \dots p.$$

V being the sum of a set of expressions derived from this by the assignation of particular values to $\alpha, \beta, \dots \lambda$; we have only to find the degree of this expression in relation to y . Now, by hyp. the dimensions (in y) of the coefficients (q) are equal to their suffixes; therefore, the dimensions of the product $q_{\alpha} - \alpha q_{\alpha} - \beta \dots q_{\alpha} - \lambda$ are

$(\alpha - \alpha) + (\alpha - \beta) \dots + (\alpha - \lambda)$, or $m\alpha - (\alpha + \beta + \dots + \lambda)$. Next, with regard to $\Sigma \alpha^2 \dots \alpha^p$; it is expressible in terms of the sums $\alpha_1, \alpha_2, \dots$ in an integer formula, which is of the degree $\alpha + \beta + \dots + \lambda$ in relation to the roots α, β, \dots , of eq. (1), as we have seen particularly in the end of sect. 11, with regard to the double and triple functions; and this expression is reducible to another, in terms of the coefficients (p) of eq. (1), which, by Newton's formula, is of the same degree, $\alpha + \beta + \dots + \lambda$, in relation to y . Adding $\alpha + \beta + \dots + \lambda$ to the quantity $m\alpha - (\alpha + \beta + \dots + \lambda)$ previously found, we obtain $m\alpha$ as the degree of the final equation. In particular cases (when the equations are incomplete), the degree may be less than $m\alpha$. Simple rules have been obtained for fixing the degree of the final equation precisely in all cases, as may be seen in a memoir by Minding in the *Journ. de Mathem.*, tome vi. The method of elimination by symmetrical functions has been extended, in a very elaborate form, particularly by Poisson, to any number of equations. But returning to the simplest case, that of two equations, it is evident that the method does not enable us to find directly the values of the second unknown which correspond to the roots of the final equation. To supply this want, Liouville has originated a beautiful method: *Journ. de Mathem.*, tome xii. He introduces a variable t , connected with x and y by the relation

$$t = x + \alpha y, \text{ or } x = t - \alpha y \quad (2.)$$

α being an indeterminate parameter. Substituting $t - \alpha y$ for x in the given equations, and eliminating y , he obtains an equation

$$f(t, \alpha) = 0; \quad (3.)$$

whence, putting $\alpha = 0$, and therefore, by (2), $t = x$, he obtains the final equation

$$f(x, 0) = 0. \quad (4.)$$

The values of y corresponding to the roots (α) of eq. (4) are obtained simply, in virtue of the relations (2) and (3), in terms of

$$\frac{d \cdot f(t, \alpha)}{d t} \text{ and } \frac{d \cdot f(t, \alpha)}{d \alpha}.$$

II. RESOLUTION OF NUMERICAL EQUATIONS.

To find the roots of an equation exactly, or approximately, when the coefficients are given numbers. This inquiry has engaged the attention of the ablest mathematicians of modern times, and it is now completely solved, at least in the most important branch of it, that concerning real roots. And what is of the greatest practical consequence, the solution has been reduced to definite arithmetical rules, which are general and simple, and in all cases easily applied. Only the more interesting investigations and results of an elementary kind can be noticed here, and these very briefly.

15. Given an equation with integer coefficients;

required the integer roots. We should naturally proceed here by trial, substituting particular integers for x , and retaining those as roots that satisfy the equation. To avoid the excessive labour often connected with such work, we may employ the method of divisors. Let

$$ax^4 + bx^3 + cx^2 + dx + e = 0,$$

be an equation with integer coefficients; and let r be a root, also an integer: then

$$\frac{e}{r} = -ar^3 - br^2 - cr - d.$$

The second member of this equation is a whole number, by hypothesis: therefore r is a divisor of e . Again, transposing $-d$ to the first side, and dividing by r , we find a quotient

$$-ar^2 - br - c,$$

which also is a whole number: therefore r is a divisor of $\frac{e}{r} + d$. Proceeding thus, we obtain

the following theorem: The coefficients of an equation being integers, and r being an integer root; r is a divisor of the last term: and if the quotient be added to the coefficient of x , r is a divisor of the sum: and if this quotient be added to the coefficient of x^2 , r is a divisor of this sum: and so on, till we reach the last quotient, which, with the coefficient of the highest power of x , gives a sum zero. The use of this theorem, in connection with our present question, is obvious; it excludes, first, all integers as not roots, except the divisors of the last term; it excludes of these all except those that fulfil the second condition; and so on, to the last condition, which excludes all integers not roots, that may have fulfilled all the previous conditions. There is another rule of exclusion, that was given by Newton, and that saves often a good deal of work. Upon the hypothesis of the former theorem; let A be the value of the first member of the equation when $x = 1$, and B its value when $x = -1$; then, A and B are divisible by $r - 1$ and by $r + 1$ respectively. The proof is left to the reader. Example:

$$x^4 - 11x^3 + 14x - 24 = 0.$$

Here $A = -20$, and $B = -48$. Of the divisors positive and negative of -24 , which are fifteen in number, the last theorem excludes all but the four, 2, 3, -3 , -4 . Observing then that the coefficient of x^2 is 0, the first theorem is applied in the following table of simple work, each second line containing the quotients:—

2	3	— 3	— 4
— 12	— 8	8	6
2	6	22	20
1	2		— 5
— 10	— 9		— 16
— 5	— 3		4
...
	— 1		— 1
	0		0

EQU

So that the only integer roots are 3 and -4. If the equation has two or more integer roots equal to each other, the above process does not determine them. But generally, when several integer roots $a, b, \&c.$, have been found, the given equation should be depressed by the removal of the factors $x - a, x - b, \&c.$, as the transformed equation is simpler and more manageable in all respects than the proposed. A very simple method of effecting this will be given in the following section. The equation being transformed in this manner, the mode of examination for equal roots is obvious: it is just a repetition upon the transformed equation, of the process formerly applied to the given one: only we may restrict ourselves to numbers which we have already found to be roots. In practice, we might proceed in an equally simple manner, by finding the successive differential coefficients $f_1(x), f_2(x), \&c.$, of $f(x)$, and then finding the integer roots, if any, common to the equations

$$f(x) = 0, f_1(x) = 0, f_2(x) = 0: \&c.$$

Having found the integer roots, and having removed the corresponding factors: required the remaining commensurable roots. These must be irreducible fractions; and the following theorem shows when there are such roots, and how they are to be found. *The coefficients of the equation being whole numbers, and that of the highest power of (x) being + 1, all the commensurable roots are integers.* For let

$$x^4 + ax^3 + bx^2 + cx + e = 0$$

be such an equation; and suppose the irreducible fraction $\frac{m}{n}$ to be a root. Substituting $\frac{m}{n}$ for x , and multiplying the equation by n^4 , we find

$$\frac{m^4}{n^4} = -am^3 - bm^2n - cmn^2 - en^3.$$

The second member is an integer, and the first is not, because m is prime to n : so that the equality is impossible; no fractional number can satisfy the given equation. Given an equation then, in the form (1), with integer coefficients; there can be no question about commensurable roots other than integers. Given an equation in any other form, reduce it first to an equation whose coefficients are all whole numbers; and then, k being the coefficient of the highest power of x , transform this equation into another (section 7) whose roots are k times greater. The final equation is of the form (1); therefore, to find all the commensurable roots of the given equation, find all the integer roots of the latter, and divide each by k .

16. To divide the first member $x^n + p_1 x^{n-1} + \dots + p_n$ of a numerical equation by $x - r$, where r is a given number; we may proceed simply as follows, by "Detached Coefficients."

EQU

$$\begin{array}{r} 1 \quad p_1 \quad p_2 \quad \dots \quad p_{n-1} \quad p_n \quad | \quad r \\ \underline{r} \quad \underline{r q_1} \quad \quad \quad \underline{r q_{n-2}} \quad \underline{r q_{n-1}} \\ q_1 \quad q_2 \quad \dots \quad q_{n-1} \quad R \end{array}$$

Write the coefficients in a line, and $+r$ to the right: multiply r by the first coefficient 1, place the product under p_1 , and add to p_1 , getting q_1 : multiply q_1 by r , place the product under p_2 , and add, getting $q_2, \&c.$, to the last sum R . The quotient required is $x^{n-1} + q_1 x^{n-2} + q_2 x^{n-3} + \dots + q_{n-1}$, and the remainder is R . The principle of the method has been stated already (section 1); but the process may be considered simply as the entire work of the division, all writing being omitted that we can safely dispense with. The utility of this short method will be better seen at a future stage: but observe here, that if r is a root, $R = 0$, and conversely; which gives a simple test for discovering integer roots, and for obtaining at the same time the depressed equations resulting from the removal of the corresponding factors. Example:

$$x^3 - 6x^2 + 11x - 6 = 0.$$

Trying the divisors $x - 1, x - 2, x - 3$, we find

$$\begin{array}{r} 1 \quad -6 \quad 11 \quad -6 \quad | \quad 1 \\ \underline{ } \\ -5 \quad -6 \quad -0 \\ 1 \quad -6 \quad 11 \quad -6 \quad | \quad 2 \\ \underline{ } \\ -4 \quad -8 \quad -0 \\ 1 \quad -6 \quad 11 \quad -6 \quad | \quad 3 \\ \underline{ } \\ 8 \quad -9 \quad 6 \\ \underline{ } \\ -3 \quad 2 \quad 0 \end{array}$$

so that 1, 2, 3, are the roots. Again, we have seen that the equation

$$x^4 - 11x^3 + 14x^2 - 24x = 0$$

has two roots, 3 and -4: required the depressed equation.

$$\begin{array}{r} 1 \quad 0 \quad -11 \quad 14 \quad -24 \quad | \quad 3, -4 \\ \underline{ } \\ 8 \quad 9 \quad -6 \quad 24 \\ \underline{ } \\ 8 \quad -2 \quad 8 \quad 0 \\ \underline{ } \\ -4 \quad 4 \quad -8 \\ \underline{ } \\ -1 \quad 2 \quad 0 \end{array}$$

so that the depressed equation is

$$x^2 - x + 2 = 0,$$

which, when resolved, gives the remaining roots of the proposed equation. After these details, we may suppose, henceforth, that our given equation has been freed from commensurable roots, and also from equal roots by the method already explained (section 8). Upon this supposition there are two principal inquiries now before us: first, the separation of the roots into real and imaginary, positive and negative, with the deter-

mination of integer limits between which the real roots are severally situated: second, the discovery of the values of the real roots to any required degree of approximation.

17. Two numbers, the one greater and the other less than the root of an equation, are called *Limits* of that root, the first a superior limit, the second an inferior. Evidently, the less the difference between the limits, the more useful they are for defining the position of the root. The only question we shall consider here is, how to determine a superior and an inferior limit of all the real roots of an equation. Of the various rules given for this purpose, the following are among the simplest and most valuable:—*The numerically greatest negative coefficient of the equation, taken positively and increased by unity, is a superior limit of all the real roots.* Again: *If the first negative term that occurs in an equation (1) be $(-p x^{n-m})$, and the greatest negative coefficient be $(-a)$; the quantity $(1 + \sqrt[n-m]{a})$ is a superior limit of all the roots.* Again: *If a number (b) , substituted for (x) , make $f(x)$ and its successive differential coefficients all positive; (b) is a superior limit of the positive roots.* Again: *If we add to unity a series of fractions whose numerators are the successive negative coefficients, and denominators the sums of the positive coefficients, including that of the first term; the greatest of the resulting values is a superior limit of all the roots.* If we had space to enter into the proof of these rules, we should only have to show, that for the value of x assigned in each case as the limit, and for all higher values, the first member $f(x)$ has values different from zero. Thus, to prove the first rule, which is due to Maclaurin, let $(-a)$ be the greatest negative coefficient: then, the quantity

$$x^n - a(x^{n-1} + x^{n-2} + \dots + 1) \\ \left\{ = x^n - a \frac{x^n - 1}{x - 1} \right\}$$

cannot be greater than $f(x)$ for any positive value of x ; for the positive and negative parts of the expression are less and greater respectively than those of $f(x)$. Therefore, we find a limit by satisfying the inequality

$$x^n - a \frac{x^n - 1}{x - 1} > 0, \\ \text{or } \frac{x^n (x - 1) - a(x^n - 1)}{x - 1} > 0, \\ \text{or } \frac{x^n (x - 1 - a) + a}{x - 1} > 0;$$

and this is satisfied if $x - 1 = a$, or $x - 1 > a$; that is, if $x > 1 + a$. The second rule is proved in the same manner: only we satisfy the inequality

$$x^n - a(x^{n-m} + x^{n-m-1} + \dots + x + 1) > 0.$$

The third rule is due to Newton. It often gives

a closer limit than any other, and is easily applied if we begin at the highest differential coefficient, and proceed regularly towards $f(x)$, enlarging the limits as we find it necessary. To prove it: diminish each root of the given equation by a quantity (e) , or substitute $y + e$ for x : the resulting equation is, by Taylor's theorem,

$$f(e) + y f_1(e) + \&c. = 0;$$

and evidently it has no positive root (y) if e be a limit according to the rule. The fourth rule is due to Bret: it is easily applied, and sometimes gives very close limits. Example:

$$x^5 + x^4 - 4x^3 - 6x^2 - 7000x + 800 = 0.$$

The superior limit found by the first rule is 7001, by the second $1 + \sqrt[5]{7000}$ or 84, by Newton's 7, by Bret's 10: the greater labour in the third case is more than compensated by the smallness of the limit. To find now an *inferior limit* of all the real roots: change x into $-y$, and find a superior limit of the roots (y) of the transformed equation. To find an *inferior limit of the positive roots*: change x into $\frac{1}{y}$, and find a superior limit (a) to the roots (y) of the transformed equation; then $\frac{1}{a}$ is the limit required, for

$$a > \frac{1}{x} \dots 1 < ax \dots \frac{1}{a} < x.$$

It is obvious that in some cases there can be no question about the limits of real roots, as when the powers of x are all even, and the coefficients all positive; in other cases, no question about the limits of positive roots, as when all the coefficients have the same sign; in other cases, none about the limits of negative roots, as when all the terms of even dimensions have one sign, and those of odd dimensions the contrary.

18. Upon the separation of the roots, we may begin with this theorem: *If $f(r)$ and $f(s)$ have contrary signs (r and s being any real numbers), the equation $f(x) = 0$ has one root or some odd number of roots between (r) and (s) ; and if $f(r)$ and $f(s)$ have the same sign, the equation has no root or some even number of roots between (r) and (s) .* It has been proved already upon simple grounds (sect. 1), that if $f(r)$ and $f(s)$ have contrary signs, the equation has at least one real root between r and s . To prove this more general theorem, let $a, b, \dots k$, be the real roots of $f(x) = 0$: then,

$$f(x) = (x - a)(x - b) \dots (x - k) \cdot \phi(x);$$

$\phi(x)$ being the product of the real quadratic factors corresponding to the imaginary roots, if there are such. We observe first that $\phi(x)$ cannot undergo a change of sign for any successive real values of (x) ; for if it did, the equation $\phi(x) = 0$ would have at least one real root (by the elementary theorem just mentioned), and $\phi(x)$

would contain a real factor $(x - l)$ of the first degree. Hence, the signs of $f(x)$ for different values of x depend only upon the signs of its factors,

$$x - a, x - b, \dots (x - k).$$

And now, if $f(r)$ and $f(s)$ have contrary signs, it is evident that one of the factors $(x - a)$, or some odd number of them, have changed their signs in the passage from one substitution $(x = r)$ to the other $(x = s)$; and therefore one of the roots, a , or some odd number of them, lie between (r) and (s) . In like manner, if $f(r)$ and $f(s)$ have the same sign, either none of the factors $(x - a)$ or an even number of them, have changed their signs in the passage from $(x = r)$ to $(x = s)$. The bearing of this theorem upon our question is obvious: but to obtain a perfect method from it, some other considerations are necessary, which will be supplied immediately. This question of separation of the roots is evidently most important; for there can be no resolution of a numerical equation till we know the number and positions of the real roots. Accordingly, the subject has been examined by able algebraists with the greatest diligence; and many interesting results have been obtained, such as the theorem of Descartes, those of De Gua, and those of Fourier contained in his posthumous work upon Equations. Referring, for a sufficient view of some of these, to Dr. Peacock's paper already mentioned, we shall present here, first, Lagrange's method, and then that of Sturm, which may be considered as superseding all others.

19. The first rigorous method of separating the roots was suggested by Waring, discovered independently by Lagrange, and expounded by the latter in his great work on the Resolution of Numerical Equations. Given a numerical equation

$$f(x) = 0; \quad (1.)$$

find a second equation

$$\phi(y) = 0, \quad (2.)$$

whose roots (y) shall be the squares of the differences of the roots (x) of eq. (1); a problem that we have noticed at sufficient length (sect. 18). By any of the methods that have been indicated (sect. 17), find an inferior limit to the positive roots of eq. (2): let it be m : then \sqrt{m} is less than the difference of any two roots of (eq. (1)). Returning to the given equation, find a superior and an inferior limit (p and q) of all its roots. Substitute now successively for x in $f(x)$, a set of numbers

$$k a, (k - 1) a, (k - 2) a, \dots \\ \dots - (k - 1) a, - k a;$$

a being equal to \sqrt{m} , or to any less number more convenient; $k a$ being not less than p , and $- k a$ not greater than q . All the real roots of eq. (1) lie between $k a$ and $- k a$; and in the interval between any consecutive pair of values substi-

tuted for x , there must be either one root or no root of eq. (1). By the theorem just proved (last sect.), the signs of $f(x)$ for the two values of x are different in the case of one root, similar in the case of no root; so that the only thing to be observed is, the succession of signs of $f(x)$ for the values $k a, (k - 1) a$, &c., of x . This is a theoretically perfect method; it detects all the real roots inevitably; and it fixes their positions by means of a superior and an inferior limit for each. The work, however, is enormous, and for equations of high degrees, impracticable. And although Cauchy has simplified the method to this extent, that we require to find only the last term of eq. (2), yet even thus the calculations are excessively tedious, and the work is transferred in a measure from one part of the process to another, as the value of the interval (a) is generally by Cauchy's method much too small. We come now to Sturm's theorem.

20. Let $f(x) = 0$ be a given equation, which has no equal roots, or has been deprived of them. Find the differential coefficient $f_1(x)$ of $f(x)$. Apply to the polynomials $f(x)$ and $f_1(x)$ the ordinary process of greatest common measure, in all its details, except that each of the remainders, before being taken as a divisor, has the signs of all its terms changed. Denote the successive remainders, with their signs changed, by $f_2(x)$, $f_3(x)$, $\dots f_{r-1}(x)$, f_r . The last remainder $-f_r$ is, by the nature of the process, independent of x ; it is also different from 0, because the given equation has no equal roots. Sturm's theorem is as follows:—In the series of functions

$$f(x), f_1(x), f_2(x), \dots f_{r-1}(x), f_r,$$

substitute any number (a) for (x) , and write in order and in one line the signs assumed by the successive functions: in like manner, substitute a second number (b) for (x) , and find a second series of signs: then, the difference between the number of variations $(+ - \text{or} - +)$ in the first series of signs, and the number of variations in the second series, is precisely the number of the real roots of the given equation which lie between (a) and (b) . For simplicity of reference, the proof will be thrown into paragraphs.

(1.) It may be assumed here (see sect. 1) that each of the functions under consideration is a continuous function of x . And therefore none of the functions (f) can undergo a change of sign (in virtue of a continuous change in the value of x), without passing through zero.

(2.) Denoting the successive quotients by q_1 , q_2 , &c., we have, by hypothesis,

$$f(x) = q_1 f_1(x) - f_2(x),$$

$$f_1(x) = q_2 f_2(x) - f_3(x),$$

$$\dots \dots \dots f_{r-2}(x) = q_{r-1} f_{r-1}(x) - f_r.$$

More generally, any three consecutive functions f_{n-1}, f_n, f_{n+1} , are connected by an equation, of the form

$$s \cdot f_{n-1}(x) = q_n \cdot f_n(x) - f_{n+1}(x); \quad (2.)$$

where s and t are positive numerical factors, introduced for convenience, as in the process of G. C. M., to prevent the occurrence of fractions.

(3.) No two consecutive functions f_{n-1} and f_n can vanish for the same value (a) of (x). For if

$$f_{n-1}(a) = 0, \text{ and } f_n(a) = 0,$$

the equation (2) gives $f_{n+1}(a) = 0$; and since the three functions f_n, f_{n+1}, f_{n+2} , are connected by an equation of the same form as (2), we find in the same manner $f_{n+2}(a) = 0$, and so on, to the last result $f_r = 0$, which is impossible.

(4.) If any intermediate function (any one of the series except the first or the last) vanishes for the value (a) of (x), the preceding function and the following have contrary signs for the value (a); and these signs are constant for all values of (x) included between an inferior limit which is less than (a) and a superior limit which is greater than (a). For if $f_n(a) = 0$, equation (2) gives

$$s \cdot f_{n-1}(a) = -f_{n+1}(a);$$

so that the two functions f_{n-1} and f_{n+1} have contrary signs for the value (a), unless they both vanish, which they do not (par. 3): and further (par. 1), the two functions preserve their signs unchanged for all values of x included between those two of the roots of the equations

$$f_{n-1}(x) = 0 \text{ and } f_{n+1}(x) = 0,$$

which are next less than (a) and next greater than (a) respectively, roots necessarily different in value from (a).

(5.) If (c) be a root of the equation $f(x) = 0$; the signs of the first two functions $f(x)$ and $f_1(x)$ change from contrary to similar, when (x) increases from below (c) to above (c). It has been already proved (sect. 1), that

$$f(x+h) = f(x) + f_1(x) \cdot h + Q h^2 + R h^3 + \&c.;$$

and

$$f(x-h) = f(x) - f_1(x) \cdot h + Q h^2 - R h^3 + \&c.$$

whence, observing that $f(c) = 0$, we find

$$f(c+h) = h \{ f_1(c) + (Q) h + (R) h^2 + \&c. \},$$

$$f(c-h) = h \{ -f_1(c) + (Q) h - (R) h^2 + \&c. \};$$

where the coefficients (Q), (R), &c., cannot be infinite. Now let h be an indefinitely small quantity. It is evident (as in the end of sect. 1) that the signs of the second members of the last two equations are the same as those of their first terms; and therefore, $f(c+h)$ has the same sign as $f_1(c)$, and $f(c-h)$ the contrary sign. And since (as in last par.), $f_1(c-h), f_1(c), f_1(c+h)$ have all the same sign; we infer that $f(c-h)$

and $f_1(c-h)$ have contrary signs, while $f(c+h)$ and $f_1(c+h)$ have the same sign.

(6.) Consider now the changes that take place in the series of signs of the functions (f), while x increases continuously through any range of magnitude. There is no change at any point of the series till one of the functions passes through zero (par. 1): we shall suppose therefore, first, that x has reached a value a for which one of the intermediate functions, f_n , vanishes. It has been proved (par. 4), that when x passes through a , the signs of f_{n-1} and f_{n+1} are unchanged, and contrary to each other; and therefore, the signs of f_{n-1}, f_n, f_{n+1} , present one variation and one permanence for values of x immediately above a , as for values immediately below a ; the change of sign of f_n having only the effect of making permanence and variation change places in three consecutive signs of the series. Hence, by the passage of x through values which cause any one or more of the intermediate functions to vanish, there is no change produced in the total number of variations. Suppose next, that x has attained a value b for which $f(x)$ vanishes. It has been proved (par. 5), that in this case, the signs of $f(x)$ and $f_1(x)$ form a variation for values of x immediately below b , and a permanence for values immediately above b ; therefore, the series of signs loses a variation when x passes through the value b . As x increases from the root b of the given equation to the root c next greater, the variations in the series of signs are not altered in number; but their arrangement is necessarily altered in such a manner, that before x reaches c , the first two signs of the series are changed from permanence to variation; and this variation is lost when x passes c . It is therefore evident, that the number of variations in the series of signs of the functions (f) is diminished by unity every time that x increases through a root of the equation, and is neither diminished nor increased in any other case: which was to be proved. This admirable theorem was presented by Sturm to the Institute of France in 1829, and published in the *Memoires* for 1835: it took its place at once in the elements as an invaluable contribution to the Theory of Equations. For various important remarks upon the theorem, and for examples, the reader must be referred to regular works, such as Young's *Treatise on Equations*. For an instructive application of Sturm's method to a particular class of equations, see Serret's *Higher Algebra*, the 13th lesson.

21. To find the values of the incommensurable roots, to any assigned degree of approximation. This is the only remaining inquiry that is of much practical interest in the theory of numerical equations, after we have seen how to detect all the real roots, and to assign special limits, a superior and an inferior, for each of them. The most natural mode of solution, and one that need not be dwelt upon, is to substitute for x in $f(x)$

a set of numbers intermediate between the two limits of the required root, till two numbers are obtained, which give results of contrary signs, and whose difference is less than the fraction that expresses the degree of approximation. Either of the last two numbers may be taken as the required approximate value of the root. To reach a result of this kind with certainty, in a regular and simple manner, and with as little work as possible; such are the objects of the higher methods of approximation. Of these methods there are three which have obtained a classical standing in the elements. The oldest is due to Newton. Let $f(x) = 0$ be the given equation: let a be an approximate value of the required root, found as above; let $a + y$ be the true value of the root. When x is changed into $a + y$, the equation becomes

$$f(a) + f_1(a) \cdot y + Q \cdot y^2 + \dots + y^n = 0, \text{ or}$$

$$y = -\frac{f(a)}{f_1(a)} - \frac{Q}{f_1(a)} \cdot y^2 - \frac{R}{f_1(a)} \cdot y^3 - \&c. \quad (3.)$$

Now if y be a small fraction, the powers $y^2, y^3, \&c.$, are much smaller, and the eq. (3) gives, nearly

$$y = -\frac{f(a)}{f_1(a)}. \quad (4.)$$

Thus; let the approximate value a be true to one decimal figure, or let y be less than .1; then $y^2 < .01, y^3 < .001, \&c.$; and therefore we may suppose generally, that the part of eq. (3) omitted in eq. (4) is $< .01$, or, that the value of y given by eq. (4) is true to two places of decimals. Find therefore the value of the quotient $-f(a):f_1(a)$ to two decimal figures, and add to a . The sum, b , is the value of the root, true to two places. For a second approximation; representing the true value of the root by $b + z$, and proceeding as before, we find

$$z = -\frac{f(b)}{f_1(b)}.$$

Calculate the value of the quotient $-f(b):f_1(b)$ to four places of decimals, and add to b . The sum c , is the value of the root, true to four places. Without more details, it will be seen that the one formula of correction is

$$y = -\frac{f(x)}{f_1(x)};$$

where x is the preceding approximate value, and y the new correction, the number of decimal figures in y being twice as many as in x . The successive approximations given by this method are far from being universally correct. The subject has been discussed at large by Lagrange, Fourier, and other more recent writers: the cases

of probable failure have been clearly fixed, and precautions of a simple kind have been indicated which are sufficient to insure a correct result in every case. And these are matters that must continue always to be of interest, on account of the great simplicity of principle, and easiness of application, that are characteristic of Newton's method. Here, however, it must suffice to observe, that each approximate value may be submitted to a simple test, which is perfectly adequate in every case, although the work be tedious. To verify the value b , (true, as we have supposed, to two decimal figures), find the values of $f(b)$ and $f(b + .01)$. If these have contrary signs, the approximation (b) is correct; if similar signs, it is incorrect: and in the latter case we must begin anew, with a more approximate value instead of a , &c. Example: required the roots of

$$x^3 - 5x - 3 = 0.$$

We find easily $+ 3$ and $- 2$ as a superior and an inferior limit of the roots. Substituting the numbers

$$- 2, - 1, 0, 1, 2, 3,$$

for x , we find the values of $f(x)$ to be

$$- 1, + 1, - 3, - 7, - 5, + 9.$$

Hence, (sect. 18), the three roots are real, one between 2 and 3, one between 0 and $- 1$, one between $- 1$ and $- 2$. To determine, first, the positive root,

$$f(2.5) = + .125; f(2.4) = - 1.176;$$

therefore, the value 2.4 of x is true to the last figure. Applying now the formula of correction

$$y = -\frac{f(x)}{f_1(x)} = -\frac{x^3 - 5x - 3}{3x^2 - 5}, \text{ we find}$$

$$x = 2.4 - \frac{f(2.4)}{f_1(2.4)} = 2.4 + \frac{1.176}{12.28} = 2.49;$$

and in verification, we find

$$f(2.49) = - .011751; f(2.5) = + .125.$$

As a second approximate value, we find

$$x = 2.49 - \frac{f(2.49)}{f_1(2.49)} = 2.49 + .0008$$

$$\therefore x = 2.4908;$$

which is true to four places, as may be verified by calculating $f(2.4908)$ and $f(2.4909)$. By changing x into $-x$, and finding the two positive roots of the transformed equation, we obtain the negative roots of the given equation: they are $-.6566$ and -1.8342 .

22. We come now to Lagrange's method of approximation; the conception of which is remarkably simple and elegant. It consists in the development of each real root under the form of a continued fraction. Compared with Newton's, this method is very laborious; but, on the other

EQU

hand, it gives approximate values that may be relied upon in all cases without discussion. In what follows, it will be assumed for convenience, that all the real roots differ from each other by more than unity. If this were not the case, we could change all the roots in any proportion, and proceed from the transformed equation. We shall suppose also, that the integer parts of all the roots have been found. Let the given equation be

$$f(x) = 0; \quad (1.)$$

and let (a) be the integer part of the required root, which may be supposed positive. Assume

$$x = a + \frac{1}{y}.$$

This expression, substituted for (x) in eq. (1), gives an equation

$$F(y) = 0, \quad (2.)$$

which is of the same degree as eq. (1), and has the same number of roots. Observing now that the roots (y) of eq. (2), when substituted in the expression $a + \frac{1}{y}$, must give the roots (x) of eq. (1); observing also that the required value of x lies between a and $a + 1$; we infer, that the required value of y is positive, and greater than 1. It is evident also that the eq. (2) can admit of only one such root; for otherwise, the eq. (1) would have more than one root between a and $a + 1$, which is contrary to the hypothesis. Hence, if we substitute for y in eq. (2) the successive integers 1, 2, 3, 4, &c., we must arrive sooner or later at two consecutive integers, b and $b + 1$, such, that $F(b)$ and $F(b + 1)$ have contrary signs. The number b so determined is the integer part of the required value of y : and we have, as a first approximation,

$$x = a + \frac{1}{b}.$$

But we may now proceed from eq. (2) in precisely the same way as we did from eq. (1). Assuming

$$y = b + \frac{1}{z},$$

and substituting for y in (2), we find an eq.

$$\phi(z) = 0, \quad (3.)$$

which has only one root greater than 1; which root is found, by successive substitutions, to lie between the consecutive integers c and $c + 1$. Assuming again

$$z = c + \frac{1}{u},$$

and substituting in (3), we find an equation

$$\psi(u) = 0, \quad (4.)$$

the only root of which, proper to the question, is

EQU

found as before, to be intermediate between the two integers d and $d + 1$; and so on. Having assumed successively

$$x = a + \frac{1}{y}, y = b + \frac{1}{z}, z = c + \frac{1}{u}, \&c.$$

we have finally

$$x = a + \frac{1}{b + \frac{1}{c + \&c.}}$$

The successive convergents $\frac{a}{1}, \frac{ab+1}{b}$, are alternately superior and inferior limits of the required root, each of them being nearer the true value of the root than the preceding: and the degree of approximation is certainly closer than that expressed by the fraction $\frac{1}{n^2}$, n being the denominator of the last convergent. These are inferences from the simplest properties of continued fractions. It only remains to observe, that for the formation of the successive equations (2), (3), &c., which is the most tedious part of the process, there is a simple and uniform course of work assigned by Taylor's theorem. Supposing the equation to be of the n th degree, and denoting the successive differential coefficients of $f(x)$ by $f_1(x), f_2(x), \&c.$, we find

$$f\left(a + \frac{1}{y}\right) = f(a) + f_1(a) \cdot \frac{1}{y} + \frac{1}{2} f_2(a) \cdot \frac{1}{y^2} + \dots + \frac{k}{y^n},$$

where k is the coefficient of x^n in eq. (1). Multiplying by y^n , and equating to 0, we find eq. (2)

$$f(a) \cdot y^n + f_1(a) \cdot y^{n-1} + \frac{1}{2} f_2(a) \cdot y^{n-2} + \dots + k = 0;$$

and similarly for the others. Example: required the positive root of the equation

$$x^3 - 5x - 8 = 0;$$

which we know to be between 2 and 3. Here

$$x = 2 + \frac{1}{y},$$

and equation (2) is found to be

$$F(y) = 5y^3 - 7y^2 - 6y - 1 = 0;$$

whence, $F(1) = -9$, $F(2) = -1$, $F(3) = +53$; and, therefore

$$y = 2 + \frac{1}{z},$$

and eq. (3) is found to be

$$\phi(z) = z^3 - 26z^2 - 28z - 5 = 0;$$

whence $\phi(26) = - (608, \phi(2=7) + 108$; and

EQU

$$z = 26 + \frac{1}{u}$$

We find thus, for x , the continued fraction

$$2 + \frac{1}{2 + \frac{1}{26 + \frac{1}{1 + \frac{1}{6 + \&c.}}}}$$

The convergents are

$$\frac{2}{1}, \frac{5}{2}, \frac{182}{53}, \frac{187}{55}, \frac{954}{383}$$

The last differs from the true value of the root by a fraction less than $\frac{1}{(383)^2}$ or $\frac{1}{146689}$.

23. We have now to notice Horner's method of approximation; and this must be done very briefly. We shall suppose that the integer part of each incommensurable root has been found in the first place by Sturm's theorem, or otherwise. We may assume also, for simplicity, that all the roots of the equation differ from each other by more than unity, and that the root required is positive, and lies between 0 and 10, so that its integer part consists of not more than one figure. Let the given equation be

$$f(x) = 0; \quad (1.)$$

and let k be the integer part of the required root. The first step in Horner's process is, to diminish each root of eq. (1) by the number k , the first figure of the required root. If we suppose $y + k$ substituted for x in eq. (1), and represent the transformed equation by

$$F(y) = 0; \quad (2.)$$

each root (y) of eq. (2) will be less than a corresponding root (x) of eq. (1) by the number k , as required. The second step is, to multiply each root of eq. (2) by 10. If we suppose $\frac{x}{10}$ substituted for y in eq. (2), and denote the transformed eq. by

$$\phi(x) = 0; \quad (3.)$$

each root (x) of eq. (3) will be ten times a corresponding root of eq. (2), as required. Now, from the nature of the process, it is evident that the root of (2) which corresponds to the required root of (1) lies between 0 and 1. It is evident also, from the hypothesis, that eq. (2) has only one root between these limits; for otherwise, some of the roots of (1) would differ from each other by less than unity. Hence, of the roots of eq. (3), that corresponding to the required root of (1) lies between 0 and 10; and eq. (3) has only one such root. The third step is, to find the in-

EQU

teger part, k , of the only root of eq. (3) that lies between 0 and 10. This number k is evidently the *second figure of the required root*. Having found k ; to carry on the approximation, proceed from eq. (3) precisely as before from eq. (1): diminish each root of (3) by k ; multiply each root of the transformed equation by 10; find the integer part, l , of the only root of the last equation that lies between 0 and 10. The number l is evidently the *third figure of the required root*, and so on. The method is very easily extended, beyond the special hypothesis that we have been proceeding upon, so as to apply to any equation, however small be the differences of the roots, and whatever be the integer part of the root required. But we have space here only for first notions. With regard to the form of the calculations, this will be best indicated by an example. Required the positive root of the equation

$$x^3 - 5x - 3 = 0;$$

which lies, as we already know, between 2 and 3. The first step, the passage from eq. (1) to eq. (2), is effected thus:

$$\begin{array}{r} 1 \quad 0 \quad -5 \quad -3 \quad \underline{12} \\ \quad 2 \quad \quad 4 \quad \quad -2 \\ \hline \quad 2 \quad -1 \quad -5 \\ \quad 2 \quad \quad 8 \\ \hline \quad 4 \quad \quad 7 \\ \quad 2 \\ \hline \quad 6 \end{array}$$

The reader will easily understand this work, if he has a distinct recollection of the method of Detached Coefficients, as explained in sect. 16, and also of the solution of problem 6 in sect 7. In the first two lines, the first member of the equation is divided by $x - 2$: the quotient is found to be $x^2 + 2x - 1$, and the remainder is -5 . In the next two lines, the preceding quotient is divided by $x - 2$: the quotient is found to be $x + 4$, and the remainder 7. In the last two lines, the preceding quotient is divided by $x - 2$: the remainder is found to be 6. Thus, the numbers ($-5, 7, 6$) at the feet of the columns, are precisely those denoted in sect. 7 by R_1, R_2, R_3 : and therefore, by the simple work above, we find the eq. (2) to be

$$y^3 + 6y^2 + 7y - 5 = 0.$$

The second step, the passage from eq. (2) to eq. (3), is effected at once, according to probl. 3, section 7. Thus, from the last equation we find

$$x^3 + 60x^2 + 700x - 5000 = 0. \quad (3.)$$

We find next the integer part, k , of the root of (3) that lies between 0 and 10, and, in continuation, we diminish each of the roots of (3) by k ; thus:

EQU				
1	60	700	— 5000	4
	4	256	3824	
	64	956	— 1176	
	4	272		
	68	1228		
	4			
	72			

This piece of work is precisely similar to the former: only, the condition by which 4 is determined to be the value of k , ought to be distinctly noticed. It is this: that 4 is the largest number of the series, 0, 1, 2, 3 . . . 9, which gives a remainder (— 1176) at the foot of the last column, having the same sign as the number (— 5000) at the top of the column; and the reader should be able, at this stage, to see the reason. We have thus found the first two figures of the root to be 2·4; and by proceeding similarly from the set of coefficients

1 720 122800 —1176000,

we should find the third figure to be 9, the fourth 0, the fifth 8, &c. Observe now that we may present the second piece of work as a continuation of the first, by affixing one, two, three, ciphers, respectively, to the numbers at the feet of the columns in the first piece, and then proceeding from these numbers as we have done in the second piece. In this manner it is evident, that however far we have to carry the approximation, we can throw the whole calculations into a continuous piece of arithmetical work, and this work as easily managed as any of the operations in elementary arithmetic. And here lies the indisputable superiority of Horner's method. There is one inconvenience incident, at first sight, to the process: as the approximation is carried on, the numbers involved in the work become very large. But this difficulty is completely removed by the use of certain contracted modes of working, which present no difficulty, and which are similar to those employed in the multiplication and division of decimals. For Horner's own exposition of the method, see the *Phil. Trans.* for 1819. For what is considered a better exposition of the whole subject, see Young's *Treatise on Equations*.

24. The only thing that remains to be noticed, on the resolution of numerical equations, is the determination of imaginary roots: but this branch of the subject is of little practical interest. When the number of real roots of an equation has been determined by Sturm's theorem, or in any other manner, it is known at once whether the equation has imaginary roots, and how many. To find such a root, when it is known to exist, substitute $a + b \sqrt{-1}$ for x in the given equation. The result is an equation

$$H + K \sqrt{-1} = 0,$$

where H and K are algebraic expressions in-

EQU

volving a and b , and independent of $\sqrt{-1}$. Any set of values of a and b that satisfy this equation, or the equivalent pair of simultaneous equations

$$H = 0, K = 0,$$

give an imaginary root ($a + b \sqrt{-1}$) of the proposed equation. According to this method, the determination of imaginary roots depends upon a process of elimination.

III. ON THE ALGEBRAIC RESOLUTION OF EQUATIONS.

The coefficients of an equation being arithmetically given, or being simply supposed known, but left indeterminate, and represented by letters; required an expression composed of the coefficients, which, when substituted for the unknown, shall satisfy the equation identically. Such is the principal question with which we are now concerned. The researches of the modern mathematicians upon this and other cognate questions form a large part of the higher Algebra. They are almost without exception much more difficult and abstract than anything we have yet had before us; they are encumbered also, for the most part, with tedious and intricate preliminary theories: so much so, that nothing more can be given here, upon the higher parts of the subject, than a slight historical sketch.

25. The roots of unity, or the roots of the equation

$$x^m - 1 = 0, \quad (2.)$$

are of such importance in what follows, that some of their properties must be noticed. First: If in the three equations

$$x^m = 1, x^n = 1, x^p = 1,$$

m and n are any whole numbers, and p their greatest common measure; the roots common to the first two equations are precisely those of the third. To prove this: Let a be any root common to the first two. Let m and n be submitted to the process of G. C. M.; and let q be the first quotient and r the remainder, so that $m = nq + r$: then

$$a^m = a^{nq+r} = a^{nq} \cdot a^r.$$

But, by hypothesis, $a^m = 1$; and therefore

$$a^{nq} \cdot a^r = 1.$$

Again, by hypothesis, $a^n = 1$; and therefore

$$a^{nq} = 1.$$

Dividing the last equation by this, we find

$$a^r = 1:$$

so that every root, a , common to the first two equations, is a root also of the equation $x^r - 1 = 0$. By a simple extension of this reasoning it appears, that every root common to the first two of the given equations is a root also of the third.

EQU

We have only to see further, that every root of the third given equation is common to the first two. Let b be any root of the third, so that $b^p = 1$: then, the numbers m and n being multiples of p , the quantities b^m and b^n are powers of b^p , that is, powers of 1, and therefore equal to 1. Which proves the theorem. Hence, if m and n are prime to each other, the first two equations have no root in common except unity. If we understand by Primitive Roots of eq. (2) those roots of (2) that do not belong to any equation of the same form and less dimensions (a definition that will be useful immediately); we infer from what has been proved, that when m is a prime number, all the roots of eq. (2) are primitive roots except unity.

Further: If a be a root of the eq. (2), every power of a is a root of the same equation. By hypothesis, $a^m = 1$. Raising both members of this equation to the n th power, we find

$$(a^m)^n = a^{mn} = (a^n)^m = 1:$$

whence, a^n , or each term of the indefinite series

$$a, a^2, a^3, a^4, a^5, \dots$$

is a root of the given equation $x^m = 1$: which was to be proved. Since the equation is of the m th degree, the series of powers of a cannot contain more than m distinct quantities, however prolonged. And this is evident otherwise, from the condition by which a is determined: for if we multiply the equation $a^m = 1$ by a , by a^2 , by a^3 , &c., we find $a^{m+1} = a$, $a^{m+2} = a^2$, &c.

Further: If m be a prime number, and a be any root of eq. (2) except unity; the m roots of the equation will be represented precisely by

$$a, a^2, a^3, \dots, a^{m-1}, a^m.$$

We have seen that each of these magnitudes is a root: we have only to see further that they are all different. Suppose that any two of them, a^p and a^q are equal. Divide the equation $a^p = a^q$ by a^q ; then, $a^{p-q} = 1$: whence, it would follow that the given equation has a root in common with the equation $x^{p-q} = 1$, which is of less dimensions. This we have seen to be impossible, m being a prime number. Therefore, all the m terms of the above series are different from each other, and each of them is a root: which proves the theorem. This does not hold when m is a compound number, and a any root of the equation. It will be seen, however, by the nature of the proof, that the theorem does hold when m is a compound number, provided a be a primitive root of the given equation. The importance of primitive roots will now be apparent: for, whatever be the value of m , if we can find one such root of eq. (2), its m successive powers will furnish all the roots of (2). If we had space for the prosecution of this subject, we would obtain several interesting theorems, almost as simple as the above, leading to this important result, that the resolution of eq. (2), when m is a com-

EQU

pound number, is reducible to the resolution of a set of equations of the same form as (2), whose dimensions are equal to the prime factors of m . Thus; if $m = p^n$, where p is a prime number; the eq. (2) is found to have a set of primitive roots, whose number is $m(1 - \frac{1}{p})$: and each of the roots of (2) is found to be expressible as a product

$$a_1 \cdot a_2 \cdot a_3 \cdot \dots \cdot a_{n-1} \cdot a_n,$$

where a_1 is any root of the equation $x^p = 1$, a_2 any root of $x^p = a_1$, a_3 any root of $x^p = a_2$, &c.: and this product is a primitive root of (2), if a_1 is different from unity. Simplifications of much the same kind are obtained, when m involves any number of unequal prime factors. With regard to the above results, it should be observed for the sake of the beginner, that the subsidiary equations $x^p = a_1$, $x^p = a_2$, &c., present no difficulty, if we know how to resolve the equation $x^p = 1$. Consider an eq. $x^m = a$: let c be the arithmetical m th root of a : introduce a new unknown, y , such that $x = cy$. The eq. $x^m = a$ becomes $c^m y^m = c^m$, or, $y^m = 1$: and the roots of the latter, multiplied by c , give the roots of the former. After these results, we may suppose m in eq. (2) to be a prime number. The only remaining question is, to resolve (2) on that supposition. The beautiful and very effective researches of Gauss upon this question will fall under our notice more properly afterwards. Meanwhile, the following elementary method is applicable in all cases. Let $m = 2n + 1$. By the theory of Reciprocal Equations, explained in (sect. 9), we can reduce the resolution of eq. (2) to that of an eq. (3) of the n th degree. It is easily proved that all the roots of (3) are real. Their values may be obtained, therefore, to any degree of approximation, by Horner's process, or otherwise, if they are not expressible by radicals; and then the roots of (2) are found at once, as they are connected with those of (3) by a quadratic equation. The resolution of (2) effected in this manner is not strictly algebraic, unless (3) is resolvable algebraically. For an excellent exposition of this whole subject, see Serret's *Higher Algebra*, the 13th Lesson, already referred to. The solution of eq. (2) by De Moivre's theorem, which is given in most books upon trigonometry, is upon the whole the best that has been obtained: but it is not in any right sense an algebraic solution.

26. We proceed to the algebraic resolution of equations of the third degree. Of the various methods that have been proposed, the following is certainly the simplest: it is due to Hudde. The equation

$$x^3 + ax + c = 0 \quad (3.)$$

is general enough in form, as the second term of the equation

$$x^3 + px^2 + qx + r = 0$$

EQU

may be made to disappear by a simple preparatory process, whatever be the coefficients (sect. 7, probl. 5). To resolve eq. (8) we assume

$$x = y + z; \quad (4.)$$

where y is a new unknown, and z a function of y to be determined afterwards. Substituting from (4) in (8), we find

$$(y + z)^3 + a(y + z) + c = 0, \text{ or} \\ (y^3 + z^3 + c) + (y + z)(3yz + a) = 0. \quad (5.)$$

If now we determine z by the condition

$$3yz + a = 0, \text{ we find } z = -\frac{a}{3y};$$

and the eq. (5) is reduced to

$$y^3 + z^3 + c = y^3 - \frac{a^3}{27y^3} + c = 0; \text{ or}$$

$$y^6 + cy^3 - \frac{a^3}{27} = 0. \quad (6.)$$

This equation, resolved as a quadratic, gives

$$y^3 = -\frac{c}{2} \pm \sqrt{\frac{c^2}{4} + \frac{a^3}{27}};$$

so that, if we represent $\frac{c^2}{4} + \frac{a^3}{27}$ by R , we find

$$y = \sqrt[3]{-\frac{c}{2} \pm \sqrt{R}}. \quad (7.)$$

Having obtained y in terms of the coefficients of (8), we find from eq. (4),

$$x = y + z = y - \frac{a}{3y}; \quad (8.)$$

so that the question is solved. The values of y given by eq. (7) are six in number as they ought to be. Thus, if p and q be cube roots of

$$-\frac{c}{2} + \sqrt{R} \text{ and } -\frac{c}{2} - \sqrt{R},$$

and if a and b be the imaginary cube roots of 1, the values of y are

$$p, ap, bp, q, aq, bq.$$

It might be thought, therefore, that the values of x determined by eq. (8) would be six in number, which they ought not. Observe, however, that the eq. (6) is not changed by the substitution of $-\frac{a}{3y}$ for y ; whence it follows that the six roots of eq. (6) are related to each other in pairs thus:

$$r \text{ and } -\frac{a}{3r}, s \text{ and } -\frac{a}{3s}, t \text{ and } -\frac{a}{3t};$$

and it is seen at once, that x , as determined by eq. (8), has one value for the first pair of roots,

EQU

one for the second, and one for the third pair, three values in all. It follows also, that in the formula

$$x = y + z,$$

considered as a solution of the question, we have to substitute for z as well as for y one of the six values of the second member of (7); and these values are to be chosen under the one condition that the product of y and z shall be equal to $-\frac{a}{3}$. Observing then that

$$pq = \sqrt[3]{-\frac{c}{2} + \sqrt{R}} \cdot \sqrt[3]{-\frac{c}{2} - \sqrt{R}} \\ = \sqrt[3]{-\frac{a^3}{27}} = -\frac{a}{3};$$

observing also, that of a and b the imaginary cube roots of unity, one is the square of the other (by last sect.), and therefore their product ab is equal to 1; we find the following to be the three values of x , the three roots of eq. (8):

$$p + q, ap + bq, bp + aq;$$

and these may be represented by one formula, usually called Cardan's:

$$x = \sqrt[3]{-\frac{c}{2} + \sqrt{R}} + \sqrt[3]{-\frac{c}{2} - \sqrt{R}}.$$

The resolution of cubic equations appears to be due to Scipio Ferrei and Tartaglia, two Italians of the sixteenth century; but how it was effected by them is not known.

27. Lagrange's method of resolving the general equation of the third degree must be noticed. Let the eq. be

$$x^3 + px^2 + qx + r = 0; \quad (1.)$$

and let its roots be x_1, x_2, x_3 . Lagrange begins by determining the value of a function t of the three roots, such, that

$$t = x_1 + Ax_2 + Bx_3; \quad (2.)$$

and from this function he obtains the expression of the roots themselves. It is evident that if the roots (x) change places in all possible ways, the function t will assume six different forms or values. Hence, the equation for determining t will be of the sixth degree. However, it will be resolvable as a quadratic if it can be obtained so as to involve no other powers of t than t^2 and t^3 ; and this is done as follows. Let A and B be the two imaginary cube roots of unity, and denote them by a, a^2 : then

$$t = x_1 + ax_2 + a^2x_3. \quad (3.)$$

Multiplying this eq. by a , and by a^2 , we find

$$at = ax_1 + a^2x_2 + x_3, \text{ and} \\ a^2t = a^2x_1 + x_2 + ax_3.$$

EQU

Comparing the second members of these three equations, we see that the last two are derivable from the first by simply making the roots (x) change places. It follows, that if we assume

$$\begin{cases} t_1 = x_1 + ax_2 + a^2x_3, \\ t_2 = x_1 + a^2x_2 + ax_3; \end{cases} \quad (4.)$$

the six values of t will be

$$t_1, at_1, a^2t_1, t_2, at_2, a^2t_2;$$

the first three of which, and the last three, are the roots respectively of the two equations

$$t^3 - t_1^3 = 0, \text{ and } t^3 - t_2^3 = 0.$$

So that the equation for determining t is of the form

$$(t^3 - t_1^3)(t^3 - t_2^3) = 0, \text{ or } t^6 - (t_1^3 + t_2^3)t^3 + t_1^3t_2^3 = 0, \quad (5.)$$

as required. To find the coefficients of (5) in terms of those of the given equation, we make use of the equations (4), together with the relation

$$1 + a + a^2 = 0, \quad (6.)$$

which is evident from this, that $1, a, a^2$, are the three roots of the equation $x^3 - 1 = 0$. Multiplying the two equations (4), we find

$$\begin{aligned} t_1 t_2 &= x_1^2 + x_2^2 + x_3^2 - x_1 x_2 - x_1 x_3 - x_2 x_3 \\ &= (x_1 + x_2 + x_3)^2 - 3(x_1 x_2 + x_1 x_3 + x_2 x_3) \\ &= p^2 - 3q. \end{aligned} \quad (7.)$$

In a similar manner, but more tediously, we find

$$t_1^3 + t_2^3 = -2p^3 + 9pq - 27r.$$

Thus, the *reducing equation* (5) is found to be

$$t^6 + (2p^3 - 9pq + 27r)t^3 + (p^2 - 3q)^3 = 0.$$

Let r_1 and r_2 be the two roots (t^3) of this quadratic: then

$$t_1 = \sqrt[3]{r_1} \text{ and } t_2 = \sqrt[3]{r_2}.$$

To find now the roots (x), we make use of the equations

$$\begin{aligned} -p &= x_1 + x_2 + x_3, \\ t_1 &= x_1 + ax_2 + a^2x_3, \\ t_2 &= x_1 + a^2x_2 + ax_3. \end{aligned}$$

Remembering the eq. (6), we find easily

$$\begin{aligned} -p + t_1 + t_2 &= 8x_1, \\ -p + a^2t_1 + at_2 &= 8x_2, \\ -p + at_1 + a^2t_2 &= 8x_3. \end{aligned}$$

In these expressions, the value of t_1 is any of the three values of $\sqrt[3]{r_1}$; but one of these being assumed, the value of t_2 or of $\sqrt[3]{r_2}$ is connected with it by the relation already found,

$$t_1 t_2 = \sqrt[3]{r_1} \cdot \sqrt[3]{r_2} = p^2 - 3q.$$

28. To resolve the general equation of the fourth degree. Ferrari's method, sometimes called

EQU

Waring's, is the oldest and simplest. Let the given eq. be

$$x^4 + ax^3 + bx^2 + cx + d = 0. \quad (1.)$$

Putting it in the form

$$x^4 + ax^3 = -bx^2 - cx - d,$$

and adding $\frac{a^2x^2}{4}$ to both members, it becomes

$$\left(x^2 + \frac{ax}{2}\right)^2 = \left(\frac{a^2}{4} - b\right)x^2 - cx - d. \quad (2.)$$

If the second member of (2) were a complete square, the equation might be depressed to the second degree by the extraction of the square roots of both members. Now, to this particular case Ferrari's method reduces all other cases by the introduction of a new unknown, z , as follows: Adding to both members of (2) the quantity

$$\begin{aligned} \left(x^2 + \frac{ax}{2}\right)z + \frac{z^2}{4}, \text{ we find the eq. } \\ \left(x^2 + \frac{ax}{2} + \frac{z}{2}\right)^2 = \left(\frac{a^2}{4} - b + z\right)x^2 \\ + \left(\frac{az}{2} - c\right)x + \frac{z^2}{4} - d. \end{aligned} \quad (3.)$$

The second member of (3) will be a complete square, if z have such a value as to satisfy the eq.

$$\begin{aligned} \left(\frac{az}{2} - c\right)^2 &= 4\left(\frac{a^2}{4} - b + z\right) \\ &\quad \left(\frac{z^2}{4} - d\right). \end{aligned} \quad (4.)$$

This, when simplified, gives the cubic eq.

$$z^3 - bz^2 + (ac - 4d)z - d(a^2 - 4b) - c^2 = 0; \quad (5.)$$

which, accordingly, is the *reducing equation* in this method. Supposing that any root of (5) has been found; put for brevity

$$\frac{a^2}{4} - b + z = \frac{m^2}{4}, \text{ and } \frac{az}{2} - c = s; \quad (6.)$$

then the condition (4) gives

$$\frac{z^2}{4} - d = \frac{s^2}{m^2}, \text{ and the second member of (3) becomes}$$

$$\frac{m^2}{4}x^2 + sx + \frac{s^2}{m^2}, \text{ or } \frac{m^2}{4}\left(x + \frac{2s}{m^2}\right)^2.$$

Therefore, the eq. (3) takes the form

$$\left(x^2 + \frac{ax}{2} + \frac{z}{2}\right)^2 - \frac{m^2}{4}\left(x + \frac{2s}{m^2}\right)^2 = 0;$$

which decomposes into the two quadratics

$$x^2 + \frac{ax}{2} + \frac{z}{2} \pm \frac{m}{2}\left(x + \frac{2s}{m^2}\right) = 0; \text{ or}$$

EQU

$$\left. \begin{aligned} x^2 + \frac{a+m}{2} \cdot x + \left(\frac{s}{2} + \frac{s}{m} \right) &= 0, \\ x^2 + \frac{a-m}{2} \cdot x + \left(\frac{s}{2} - \frac{s}{m} \right) &= 0 \end{aligned} \right\} \quad (7.)$$

Since the roots of the cubic equation (5) are expressible algebraically in terms of the coefficients of the given eq. (1), it follows that the roots of (1) have the same property; for by means of the last two equations (7), we can express the four roots (x) of eq. (5), which are just the roots of (1), in terms of s and the coefficients of (1). The question, therefore, is solved, but the expressions of the roots are excessively complex. Other solutions, quite distinct from the above, and from each other, have been given by Descartes, Euler, and Lagrange. Looking back to the reducing equation (5), and remembering how Lagrange obtains the reducing equation in the resolution of the equation of the third degree, we may inquire here what function s is of the roots of eq. (1). Let x_1, x_2 , and x_3, x_4 , be the roots of the two equations (7). Then, these are the roots of eq. (1); and from the equations (7) we find at once

$$x_1 x_2 + x_3 x_4 = \left(\frac{s}{2} + \frac{s}{m} \right) + \left(\frac{s}{2} - \frac{s}{m} \right) :$$

whence $s = x_1 x_2 + x_3 x_4$.

This reducing function, s , or $x_1 x_2 + x_3 x_4$, is of such a form, that if the roots (x) change places in all possible ways, it assumes only three distinct values: and hence we might infer, *a priori*, that the equation for the determination of this function must be of the third degree, as the eq. (5) is in fact. To this circumstance, that we can form a function of four letters which has only three values, is the success of Ferrari's and of every other known method to be attributed; for hence it is that the resolution of biquadratics is reducible to that of cubics. In Lagrange's method, the reducing function is $x_1 x_2 + x_3 x_4$, the same as in Ferrari's. There are other functions, almost equally eligible, such as

$$y = x_1 + x_2 - x_3 - x_4,$$

which is the reducing function in Euler's method. It admits evidently of six different values; but since these are equal and of contrary signs by pairs, the reducing equation of the sixth degree can contain no odd power of y , and may therefore be resolved as a cubic in y^2 . The reducing function in Descartes' method is

$$u = x_1 + x_2.$$

It admits of six different values $x_1 + x_2, x_1 + x_3$, &c.; so that the reducing equation is of the sixth degree. But if we have previously deprived the equation of its second term, which may always be done, we shall have

EQU

$$\begin{aligned} x_1 + x_2 + x_3 + x_4 &= -p = 0, \text{ or} \\ x_1 + x_2 &= -(x_3 + x_4), \end{aligned}$$

so that the values of u are equal and of contrary signs by pairs, and the same remark applies to the reducing equation in this case as in the last. In like manner, the success of Hudde's method and of Lagrange's, in the resolution of cubic equations, depends upon this, that we can form functions of three letters which admit of only two values, by permutations of the letters. Thus, with regard to Lagrange's reducing function t , we have seen that

$$t^3 \text{ or } (x_1 + a x_2 + a^2 x_3)^3$$

admits of only two values; and the same is true of the reducing function y (sect. 26) employed in Hudde's method.

29. The algebraic resolution of an equation is effected, according to every method yet known, by being made to depend upon that of another equation which is more easily resolved, and whose root is a function of those of the original equation. Upon this general view of the subject large developments were given by Lagrange, especially in those famous researches that were published in the *Memoirs of the Academy of Berlin* for 1770 and 1771. He proved that all the known processes for the resolution of quadratic, cubic, and biquadratic equations, however different in appearance, were virtually dependent upon a common principle, and reducible to one general method. He then extended the method to the general equation of the m th degree, by the employment of a reducing function, t , of the form

$$x_1 + a x_2 + a^2 x_3 + \dots + a^{m-1} x_m,$$

where x_1, x_2 , &c., are the roots of the given equation, and a a root of the equation $x^m = 1$. He found that, when m is a prime member, the resolution of the reducing equation, which is generally of the degree 1. 2. 3. . . . m , is reducible to the resolution of another equation whose degree is $m - 1$, and whose coefficients depend upon an equation of degree 1. 2. 3. ($m - 2$). Results of an equally definite kind were obtained for composite values of m ; but it would be of little use to present them here. Generally, when the given equation is of a degree higher than the fourth, the reducing equation found by Lagrange is of a still higher degree, and does not appear to be generally susceptible of depression: a result that almost decides the question of the resolvability of general equations of higher degrees than the fourth, so far at least as the above form of reducing function is concerned, so far, we might even say, as all known principles of resolution are concerned. In Lagrange's work on the Resolution of Numerical Equations, the 14th note, his method is applied in a very elegant manner to the resolution of Binomial Equations, a question that had been solved before by Gauss.

80. Why is it that the general equations of the first four degrees are algebraically resolvable? To this question Lagrange gave a most suggestive answer in his researches last mentioned. As a result of his analyses, and in the distinctest manner, he connected the property of resolvability of an equation with certain properties possessed by functions of sets of letters, in relation to permutations among the letters; a subject upon which a few hints have been just given in the end of sect. 28. The equations of the third and fourth degrees are algebraically resolvable, because we can form functions of three letters which have only two values, and functions of four letters which have only three. And if we could form functions of five letters, having only four or three values, we have reason to believe that such functions would enable us to resolve the general equation of the fifth degree. Here a new line of investigation was presented to mathematicians, and a very difficult one. Lagrange himself discovered one theorem upon the subject, which is, That the entire number of values which a function of n letters can assume, in virtue of permutations among the letters, is either equal to

$$1. 2. 3. \dots n,$$

or some submultiple of this number. Ruffini advanced another step: in his *Theory of Equations* he considered particularly functions of five letters, and he seems to have succeeded in proving, though in an excessively complex manner, That if a function of five letters has less than five distinct values, it cannot have more than two. Ruffini's is a case of the following theorem, which has been obtained very recently: n being greater than 4, a function of n letters which has less than n distinct values, has two values at most. The subject has been studied carefully and with success by several eminent mathematicians, Abel, Cauchy, Bertrand, and Serret. The results yet obtained, as well as the principal modes of investigation, are presented fully, and in a very interesting form, in Serret's *Higher Algebra*. Much apparently remains to be done in this field, but enough has been obtained for the object with which the inquiry originated. From Ruffini's theorem, for instance, though we cannot infer strictly that the general equation of the fifth degree is irresolvable, we do infer that it cannot have a reducing equation of a lower degree than the fifth.

81. These considerations lead only to a strong presumption; and, accordingly, they have not been found sufficient to deter sanguine algebraists from attempting the resolution of the general equation of the fifth degree. Among others, the illustrious Abel made the attempt; and the result of his investigations was, a rigorous proof of the impossibility of resolving algebraically a general equation of any degree above the fourth. In this demonstration it is shown,

that the assumption of the algebraic resolvability of a general equation of the fifth or higher degree leads to an impossibility: while a similar assumption for general equations of the second, third, and fourth degrees, leads to this result, that the first radical (in the order of operation) which is involved in the expression of the root must be a square root, and the second radical a cube root; conditions fulfilled in fact by Cardan's formula, and by every other algebraic expression of the roots of equations that has been yet obtained. Abel's proof has been simplified in some points by Wantzel; but as it stands at present, the principles involved in it are so very high and general as to throw it quite out of elementary science: and perhaps there is no remedy. It will be seen that the question is one of extreme generality, being properly this: Is there any algebraic function whatever of the coefficients, which, when substituted for x , shall satisfy the equation identically? It is evident that one of the first things to be done towards the solution was, to study the general form of algebraic functions. This was done by Abel: he examined and classified algebraic functions; he distinguished them as of different degrees and orders, according to the number of radicals involved in them, and the number of times that the radicals succeed one another, or are superposed upon each other: he obtained finally a general expression, comprehensive of all possible algebraic functions of a set of magnitudes. Having assumed that such an expression, substituted for the unknown, would satisfy the equation, he obtained the following result: If an equation is resolvable algebraically, such a form can be given to the root that all the algebraic functions of which it is composed shall be rational functions of the roots of the given equation. This theorem, with some others upon the changes of value undergone by a function of several letters in virtue of permutations among the letters, constitute the main principles of the demonstration.

82. The researches of Gauss upon the resolution of Binomial Equations, were published in 1801, in his *Disquisitiones Arithmeticae*; and gave a large extension and a powerful impetus to algebraic science. He proved that the equation to which we are led by the problem of the division of the circle into a prime number n of equal parts is always resolvable by radicals; and that the index of each of the radicals involved in the expressions of the roots is a prime factor of the number $n - 1$. A few notions will be now presented upon the elements of this remarkable method. It has been proved already (sect. 25), that if r be any root of the equation

$$\frac{x^n - 1}{x - 1} = 0, \dots \quad (1.)$$

when n is a prime number; the entire system of the roots may be represented by the series

EQU

$$r, r^2, r^3, \dots, r^{n-1}, \quad (2.)$$

or by the series of powers of r whose indices form the arithmetical progression

$$1, 2, 3, 4, \dots, (n-1). \quad (3.)$$

Gauss represents the roots by the series

$$r, r^a, r^{a^2}, r^{a^3}, \dots, r^{a^{n-2}}, \quad (4.)$$

or by the series of powers of r whose indices form the geometrical progression

$$1, a, a^2, a^3, \dots, a^{n-2}. \quad (5.)$$

Where it is to be remarked, as essential to the method, that the number a is a *primitive root* of n , or a number such, that all its powers from the 1st to the $(n-1)$ th, divided by n , leave different remainders, that for the $(n-1)$ th power being 1. The properties of primitive roots of n , as well as their existence for every value of the prime number n , are proved in all the books on the Theory of Numbers. Assuming the properties of a above stated, we obtain the following theorems:—1st, If the index of r in any term of series (4) leave a remainder s when divided by n , the term itself is equal to r^s . For if m be the quotient, the term is r^{ma+s} , which $= r^{ma} \cdot r^s = r^s$, because by hypothesis, $r^n = 1 = r^{ma}$. We may call r^s the reduced form of the corresponding term of (4). 2d, All the roots of eq. (1) are represented by the series (4). To see this, conceive another series (6) drawn out, consisting of the reduced forms (r^s) of the terms of (4). The indices s in series (6) must be all different from each other, because a is a primitive root of n ; they are all integers, less than n , and their number is $n-1$. It follows that the indices of r in series (6) must form the entire series of numbers $1, 2, 3, 4, \dots, (n-1)$. And hence, each term of series (4) has a corresponding equal term in series (2), which proves the theorem. 3d, If the series (4) be indefinitely prolonged, it simply repeats itself. Each term of (4) is a constant function (the a th power) of the preceding term. Suppose the series (4) prolonged according to this law, and the series (5) along with it. The next term of (5) is a^{n-1} . By a property of primitive roots of n already mentioned, the number a^{n-1} divided by n leaves a remainder 1. Therefore, the first term in the prolongation of the series (4) is, in its reduced form, r ; which proves the theorem. 4th, If $n-1 = h \cdot k$, h and k being whole numbers: the series (4) may be thrown into h groups or into k groups of terms, each group forming a series which proceeds according to the same law as the series (4), (each term a constant power of the preceding), and which possesses the same property of self-repetition. It will be sufficient in the proof to consider the indices of the terms. Putting $a^h = m$, we may

EQU

write the series (5) in a succession of vertical columns thus:

$$\begin{array}{ccccccc} 1 & m & m^2 & \dots & m^{h-1} \\ a & m a & m^2 a & \dots & m^{h-1} a \\ a^2 & m a^2 & m^2 a^2 & \dots & m^{h-1} a^2 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ a^{h-1} & m a^{h-1} & m^2 a^{h-1} & \dots & m^{h-1} a^{h-1} \end{array}$$

The index of a in the last term is $h(k-1) + h-1$, which $= h \cdot k - 1 = n-1$, as it ought. Consider the first horizontal line; collect the corresponding set of terms out of series (4) in order: the result is, a series of h terms, each term the m th power of the preceding: and if this series be prolonged, the next index is m^h , which $= a^{h \cdot h} = a^{n-1}$, so that the series repeats itself. A similar series is found from the second line; and if it be prolonged, the next index is $m^h \cdot a$, which $= a^{n-1} \cdot a$. Now this divided by n leaves a remainder a , because the factor a^{n-1} divided by n leaves a remainder 1: so that the second series repeats itself. Similarly for all the lines. We have thus distributed the terms of series (4) into h groups of k terms, each group possessing the properties assigned. We could have distributed them likewise into k groups of h terms. And it is obvious that if h and k are composite numbers, the groups just obtained may be distributed each into a set of subordinate groups possessing the same properties, and so on; there being no stop to the process till we reach the prime factors of $n-1$. 5th, If the sum of the roots of eq. (1) be divided into parts, or periods, corresponding to the groups considered in the last proposition, the continued product of any number of the periods will be equal to the sum of a certain number of the same periods. This is the fundamental principle of reduction in Gauss's method. To prove it, consider merely the indices; and represent two of the periods, which are to be multiplied together by the two series

$$\begin{array}{l} b, b m, b m^2, \dots, b m^{h-1}; \\ c, c m, c m^2, \dots, c m^{h-1}; \end{array}$$

which are two of the lines of last proposition, b and c being some powers of a . We find as a first part of the series representing the product, the set of quantities

$$(b+c), (b+c)m, (b+c)m^2, \dots, (b+c)m^{h-1}.$$

As a second part (by adding each term of the lower line to that in the upper line one place to the right), we find

$$(b m + c), (b m + c)m, \dots, (b m + c)m^{h-1}.$$

As a third part (by taking terms two places to the right),

$$(b m^2 + c), (b m^2 + c)m, \dots, (b m^2 + c)m^{h-1}.$$

By reference to the properties already proved, it will be seen that the k groups of terms thus found constitute the whole set of indices which represent the required product. It will be seen also that each of these groups represents some one of the k original periods. The proposition being proved for the product of two periods, it follows easily for the continued product of any number. It is evident now, that whatever be the prime number n , we can find (sect. 5) the coefficients of an equation whose roots are equal to the periods which we have been considering. In this manner we can depress the given equation to one whose degree is equal to the greatest prime factor of $n - 1$: which is the most interesting result of Gauss's method.

For example, the equation

$$x^{17} - 1 = 0$$

may be resolved (its roots expressed by radicals) by the resolution of several quadratics. For a simple exhibition of the work, see Hymers on Equations, Sect. 4.

83. In what cases can an equation be resolved algebraically? This is the highest question that has occurred in the theory of equations, and the solution of it is not yet completed. Many researches have been made upon it, at the head of which, as starting points, must be placed those of Lagrange, already noticed (sect. 29), and those of Gauss upon Binomial Equations. Abel's theorem upon non-resolvability was a very important step towards the solution, as it puts out of question all equations of the fifth and higher degrees, with indeterminate coefficients. The next advance made was a very remarkable one. We have seen that in the series of the roots of a binomial equation, as arranged by Gauss, each root is a constant power of the preceding, the first root being this same power of the last. Abel generalized upon this hint. He showed that when each of the m roots, $x_1, x_2, x_3, \dots, x_m$, of any equation is a constant rational function of the preceding, this function of x_m being farther equal to x_1 , the equation is resolvable by radicals: also, that if two roots of an irreducible equation of prime degree be so connected that the one is expressible rationally as a function of the other, the equation may be resolved by radicals. (By an irreducible equation is meant one whose first member admits of no *commensurable divisor*, no divisor whose coefficients are rational functions of given numbers.) Abel improved upon Gauss's theory: he gave it completeness and symmetry, and made many valuable additions. The next important step was taken by Galois, who proved the following beautiful theorem:—To render an irreducible equation of prime degree resolvable by radicals, it is necessary and sufficient that any two of the roots being given, the others be deducible from them rationally. The inquiry has been prosecuted more recently by Kronecker, and with much success. But as the

space properly allowable for this article is now more than occupied, we must refer the reader, for a full account of Kronecker's researches, to the second edition of Serret's *Algebre Supérieure*.

Standard English works upon the subject: Peacock's *Algebra*; *Treatises on Equations* by Hymers, Young, Murphy (*Library of Useful Knowledge*), Ivory (*Encyclopædia Britannica*). The last is a very masterly production.

Equations of Condition. The Equations so designated arise as follows:—The aim of observation and experiment generally is to determine unknown quantities connected with each other by some such relation as this:

$$ax + a'y + a''z = 0.$$

The quantities whose value is sought, (x, y, z) can rarely be determined directly, but it is usually possible to find numerical values for a, a', a'' , &c. in separate cases. It is easy to see that if these numerical values were absolutely correct, three sets of experiments or observations would yield three equations, and therefore suffice for the determination of the three quantities, x, y , and z . But the experimental valuation of a, a' , and a'' , is always subject to error; and it is not therefore held sufficient to obtain only three equations. We have thus a case, exactly the reverse of that of *Indeterminate Equations*, i. e., we have many more equations than there are unknown quantities; and the question is, how shall these equations be combined so that the most accurate attainable values of x, y , and z be extracted from them? The mode of combination indicated by the term *Equations of Condition* is exceedingly simple. Suppose, for instance, that we had obtained nine numerical equations, these may be reduced to the requisite three, by a process of simple addition, viz.—

$$\begin{aligned} (1) + (2) + (3) &= 0 \\ (4) + (5) + (6) &= 0 \\ (7) + (8) + (9) &= 0; \end{aligned}$$

or, again,

$$\begin{aligned} (1) + (4) + (7) &= 0 \\ (2) + (5) + (8) &= 0 \\ (3) + (6) + (9) &= 0, \end{aligned}$$

and also in other forms. The mean of the different values of x, y , and z , will generally be pretty near the true value. It is necessary, however, to take account of the *weight* or relative importance of the several observations or experiments, and to express that relative importance numerically.—Let us follow an example of the determination of an unknown quantity, by three methods—the ordinary method, or that of the *Mean*; the method just indicated; and the method of the *Least Squares*. See MEAN, and SQUARES THE LEAST. Suppose we have three equations,

EQU

$$\begin{aligned}x - 1 &= 0 \\10x - 11 &= 0 \\20x - 24 &= 0.\end{aligned}$$

By taking the mean, we find

$$x = 1.1.$$

By the foregoing method,

$$x = 1.16.$$

By the method of Least Squares,

$$x = 1.17.$$

The errors or discrepancies between these results and the three equations are as follows:

$$\begin{aligned}\text{I. } &= + .1 : s' = 0 : s'' = - 2.0 \\ \text{II. } &= + .16 : s' = .6 : s'' = - 0.8 \\ \text{III. } &= + .17 : s' = .7 : s'' = - 0.7.\end{aligned}$$

There is a very serious error in the first determination as regards the third equation. The method illustrated in this article compares favourably with the method of the least squares; but the case given is not exactly a fair one.

Equation, Annual, refers to the motion of the moon round the earth. When the sun is at different distances from the earth it produces different effects of perturbation on the earth's position and on the moon's generally. It is not at the same distance from each, and does not attract them equally or make them preserve their relative positions. Thus, supposing the moon to remain constantly moving in an ellipse round the earth—which would be something like the case if they remained in a constant relative position—the inequality of position may be conceived to shift the position of the earth from the focus on either side; sometimes taking it farther from the moon, at other times bringing it nearer. Supposing the moon to describe the same spaces in her revolution in the same times, it is clear that the earth being thus at different distances from her, she will seem to a spectator to go faster when she is nearer than she does when she is farther away. She would seem to do so, even if the earth were fixed in the focus, but manifestly not in the same degree. This is the origin of the *Annual Equation*. See *LUNAR THEORY*.

Equations, Functional. A special kind of equations, in which there is no limit whatever to the form in which the relations of the unknown or unknowns may be stated. In algebraical equations, they are connected by any of the ordinary algebraical or arithmetical processes, addition, subtraction, multiplication, division, involution and evolution. Here, there is no such necessity—the unknown is, besides, rather a *form* than a number or magnitude in this case. Thus the following is a functional equation:—Required such an algebraical expression as will be increased by 1, whatever value is assigned to x , when x^2 is substituted for x . It is stated so

$$\phi(x^2) = \phi(x) + 1. \text{ Required } \phi(x).$$

EQU

The solution of such questions is the object of the calculus of functions. See *FUNCTIONS*.

Equator, Celestial. That great circle in the sky, which represents the prolongation of the plane of the Equator of the Earth.

Equator, Terrestrial. The great circle on the Earth's surface, half-way between the two Poles. It divides the Earth's surface into the Northern and Southern Hemispheres.

Equatorial, or Equatorial Telescope. An Equatorial Telescope is a telescope so mounted as to have two axes of motion at right angles to each other; each axis carrying a graduated circle, and one of them being parallel to the axis of the Earth. In the adjoined cut, the

two axes are represented carrying the graduated circles x and y ; and the axis, A , points to the pole of the Earth's axis. The consequence of this latter provision is, that as soon as the telescope is fixed on a star, it may be clamped at the

circle D; for by moving simply around the axis A, it will follow that star,—inasmuch as this axis A, is really the axis of that diurnal motion of which the star partakes. To keep the star in the field of view, it is thus needful to move the telescope in one direction only; and further, it must—since the diurnal motion of the heavens is uniform—be moved with entire uniformity round A; so that it may be moved by *clock work*. A clock, whose weights are at G, is now accordingly always attached to the axis A; and thus, after having once fixed the telescope on an object, the Observer is freed from all anxiety regarding its motion: the mechanism retains the telescope on the object; and he is not further diverted from the task of examining its nature, or ascertaining its dimensions by the microscope at the eye-piece. It were impossible to exaggerate the importance of this instrument, which has deservedly become a prime one in Observatories. There are various forms of mounting—the one in the cut being that applied by Fraunhofer in the first place, and subsequently by Merz, to the superb Refractors constructed at Munich. Other modes have also been found successful, especially the one applied by Mr. Lassell to his very large and heavy Reflector. — On the attached circles, the *Declination* and *Right Ascension* are marked by graduations of the requisite fineness; D being the declination circle, and B the circle on which the Hours of Right Ascension are indicated.—All Equatorials demand the following adjustments:—1. The Polar axis must be parallel to the axis of the Earth. 2. The index of the declination circle must point to zero, when an Equatorial star is in the centre of the field of view. 3. The line of collimation of the telescope must be perpendicular to the declination axis. 4. The declination axis must be perpendicular to the polar axis. 5. The index of the hour circle must point to zero, when the telescope is in the meridian of the place.—All these adjustments may be attained by suitable observations; and if error remains in either, it can be corrected by appropriate formulæ, to be found in any work on *Practical Astronomy*.

Equilibrium, Technical. The state of rest of a body or system, solicited by various forces. The science which treats of the equilibrium of bodies is *STATICS*.

Equinoctial. A synonym for the Equator, both of the earth and of the heavens. When the sun's diurnal path is along this circle there is equal length of day and night all over the world; and from this comes the name.

Equinoctial Time. As the date of a phenomenon is a fact of great importance in all physical, and especially in astronomical investigations, and as local measurements of time date from circumstances purely local, it is desirable that some instant should be selected as the central point of a uniform reckoning of time. The moment when the point of Aries passes the vernal equinox is

taken as this starting point; and time dated from that, is called equinoctial time.

Equinox. The points where the ecliptic and equator cut one another in the sky are called the equinoxes, because when the sun is in them he appears, in consequence of our rotation, to describe the circle of the equator, and the day and night are equal over the world. When he is passing up from south to north he passes the *vernal* equinox (when the days are lengthening), and in passing from north to south, the *autumnal* equinox (when the days are shortening). The dwellers in the southern hemisphere have our vernal for their autumnal equinox, because while the sun is south of the equator daily, the days are long to them, and short to us. The point of the equinox does not remain stationary. Its motion is due to the perturbations of the planets, which cause the ecliptic to move; and nutation and precession both operate. See these articles.

Equivalent, Joule's.—Nearly two centuries have passed since Locke gave a definition of heat, which he probably derived from Bacon.—“Heat is a very brisk agitation of the insensible parts of the object, which produces in us that sensation from whence we denominate the object hot; so what in our sensation is *heat*, in the object is nothing but *motion*.” If we add Newton's definition that the force possessed by matter is its power to persevere in its state of rest or motion; and his third law: that reaction is equal and contrary to action, a law including what is now called *conservation of force*—it is evident that at this early period the principles of a true doctrine of heat were enunciated. In the year 1798 Benjamin Count Rumford published his *Inquiry Concerning the Source of Heat which is Excited by Friction*. He caused a blunt steel borer to revolve with great friction in a hollow cylinder of iron. An amount of heat was thus generated, the experiment being sometimes carried on until water in contact with the metal was made to boil. Rumford carefully examined whether any other thermal source existed, as change of specific heat of the iron, oxidation by contact with air, &c., but found no reason to suspect that such was the case. He therefore concluded that it was “extremely difficult, if not quite impossible, to form any distinct idea of anything capable of being excited, and communicated, in the manner the heat was excited and communicated in these experiments, except it be motion.” Further, Rumford gave figures which expressed the relation between the work spent and the heat evolved in his experiments. The heat he estimates at 180° Fahr., in 26.58 lbs. of water; the power, barely that of one horse for two hours and a-half. If we estimate the power at $\frac{3}{4}$ that of one horse, or 24,750 foot pounds per minute, we shall obtain

$$\frac{24,750 \times 150}{180 \times 26.58} = 776,$$

which is almost identical with the now ascertained equivalent.

It does not seem that any further step was taken to evaluate the mechanism of heat until Séguin published his work on Railways, in 1839. In it he states (p. 382) his belief that a certain quantity of caloric disappears in the very act of the production of mechanical force, and *vice versa*, and that the two phenomena are united to "each other by conditions which assign them invariable relations;" also at page 388 he observes, "that the mechanical force which appears during the lowering of the temperature of a gas, as of every other body which is dilated, is the measure and the representation of the diminution of heat." He then proceeds to state that the mechanical "effect obtained by the expansion of a cubical metre of vapour compressed by a weight of two kilogrammes on the square centimetre, when it is allowed to expand into a space corresponding to a pressure of one kilogramme, and a lowering of temperature of 20° , is represented by a weight of 6.618 kilogrammes raised to the height of one metre."

In 1842, Dr. Mayer published a paper entitled, "Remarks on the Forces of Inorganic Nature," in which, without actually going beyond Séguin, he stated the mechanical theory more explicitly, and with greater perspicuity. "Forces," he says, "are causes in which the principal *causa equat effectum* must fully hold. If a cause c produce an effect e , then $c = e$. If the cause c has produced the work e equal to it, then the cause c will have stopped, c has become changed to e , and therefore we must view c and e as different forms of one and the same object." Is the case of the fall of heavy bodies the effect is heat. Adopting the hypothesis advanced by Séguin, Mayer assumes that the force employed to compress a gas is equivalent to the heat given out, and thence infers that "the fall of a weight from the height of about 865 mètres "corresponds with the elevation of a like weight of water from 0° to 1° ."

It must always be matter for wonder that the work of Count Rumford attracted so little of the attention it deserved. This may be ascribed to the strong hold which the theory of caloric had upon the minds of philosophers, or perhaps that his experiments were not deemed sufficiently complete. The speculations of Séguin and Mayer have far less claim to be received as proofs of the mechanical nature of heat, or as affording sure grounds for the establishment of a numerical relation between heat and force. These speculations, so far as regards the nature of heat, are founded upon the hypothesis of the indestructibility of force, which, though apparently self-evident, and generally received by philosophers as axiomatic, nevertheless was capable of, and required experimental proof. Then an attempt is made to estimate the mechanical equivalent of heat by using the further hypo-

thesis that in compressing an elastic fluid the heat generated is the force which has been expended. This last hypothesis has since been shown to be approximately true; but at the time it was advanced by Séguin and Mayer the published results of experiments led to a different conclusion. From all that was then known, it was impossible to predicate with certainty that it held even approximately. That such an hypothesis could not be safely received without experimental proof, is evident from the consideration that it is possible to conceive an elastic fluid, obeying the gaseous laws, which on compression shall give out no heat whatever, or even shall produce cold.

The researches of Joule date from the year 1840. In the first instance their object was to examine the relation of electricity to heat. He found that the heat evolved by a voltaic current arose solely from the resistance it experienced in passing through the wire or fluid conductor; so that, by increasing the electro-motive force, which permitted the use of a circuit of greater resistance without diminishing the flow of electricity, any amount of heat could be obtained from the same quantity of electricity. As a consequence of this law it immediately followed—1st, That, whether the circuit was composed of good or bad conductors, the same quantity of heat would be invariably produced by a given chemical effect in the battery. 2d, That the heat produced by a voltaic couple is proportional to the intensity of its electro-motive force. 3d, That the heat produced by the combustion of a metal in oxygen gas is proportional to the intensity of the force with which the elements combine, and may be calculated in the same way as if the oxygen and metal were a voltaic couple, the poles of which were connected by a resisting metallic wire. All these laws point to the conclusion that heat is derived from mechanical action, and accordingly Joule proceeded to search for the means of determining the absolute relation between the two. These he found to be presented by the electro-magnetic machine or engine. An electro-magnet, furnished with the means of reversing the current at every half revolution, was placed on a vertical axis, between the poles of a powerful magnet. When a voltaic current was made to traverse the electro-magnet, it revolved with great velocity, *developing a considerable amount of mechanical force*. At the same time the *flow of electricity was reduced in quantity* in a certain proportion as the velocity and work increased. Now Joule had already found that the quantity of heat evolved by a conductor was proportional, in a given time, to the square of the quantity of current. But, the quantity of chemical action being simply proportional to the current, according to Faraday's law, it followed that, if the evolution of heat in the revolving apparatus was governed by the same law which obtained in a stationary circuit,

there must be less heat evolved for a given chemical action when the machine was at work than when it was at rest. An examination of the heat evolved by the coils of the electromagnet while rotating proved that this was the fact; and on comparing the defalcation of heat with the force developed, a mean of two results showed that—I. For every degree of heat per pound of water expended, 806 pounds were raised to the height of 1 foot by the work of the engine. By turning the machine in the contrary direction there was an expenditure of force, an increase in the flow of electricity, and an increase of heat over and above that due to the chemical action of the battery. In this case a mean of four experiments indicated that—II. A pound of water was raised one degree by the expenditure of a mechanical force, in turning the machine, capable of raising 962 pounds to the height of one foot. In the course of experiments, Joule had discovered that when a bar of iron is rotated between the poles of a magnet it becomes heated, the effect being considerably increased by coating it with a conducting substance, such as copper. He found, at the same time, that force was used up, and it thus appeared from a mean of seven experiments that—III. Each degree of heat required the expenditure of a force able to raise 776 pounds to the height of one foot. This last equivalent was considered to be more correct than the previous ones, on account of the greater facility with which the experiments were made. In the same paper, which was published in 1848, it is stated that its author had proved experimentally that heat is evolved by the passage of water through narrow tubes, and that—IV. In this way he had deduced for the mechanical equivalent of heat, a term which he himself was the first to employ, the number 770. An experimental investigation on the changes of temperature produced by the rarefaction and compression of air, communicated to the Royal Society in 1844, led the same author to the belief that the relation between the heat absorbed and the work performed, or between the heat evolved and the work expended, was the same as he had obtained from the electro-magnetic experiments, and he therefore concluded that the hypothesis of Séguin and Mayer, of whose writings he appears to have been then ignorant, was sensibly correct. The numbers obtained for the equivalent were—V. In the experiments on compression, 809, and—VI. In the experiments on expansion, which were susceptible of greater accuracy, 798. It was at the same time proved that no appreciable absorption of heat took place when air expanded without performing work. This has been since shown by experiments devised by Thomson, and carried out by him and Joule, to be only approximatively correct. It had frequently been observed that the temperature of the sea was raised after long continued agitation in stormy weather. About the

year 1840, Mr. Dyer had an apparatus constructed for the agitation of water, in which he observed the development of heat to take place. Mayer soon afterwards announced that he had thus raised water from 12° to 18° . Others, however, denied these results. Joule now returned to methods that had occupied him in 1843. His new apparatus consisted of a paddle wheel working in a vessel containing the fluid. Three researches, successively improved in accuracy, gave—VII. For the mechanical equivalent derived from the agitation of water, the numbers 890, 781, and 772. A series of experiments gave—VIII. For the equivalent obtained from the friction of oil, 782. Two researches, successively improved in accuracy, gave—IX. For the agitation of mercury, the equivalents 787, and 774—Lastly, a series of experiments gave—X. As the result of the friction of cast iron, the number 775.

Eriometer. An instrument of some importance and high interest, invented by Dr. Thomas Young.—It has been explained under DIFFRACTION, how, if a divergent ray of light passes the borders of a hair, or fine iron thread, a series of coloured parallel fringes will be found on the edges of the shadow. Now, the distances of these fringes from the shadow, and from each other, increase as the diameter of the thread diminishes; and if, instead of a thread, a number of threads be used, crossing or interlacing with each other, the coloured fringes will be changed into concentric circles, like halos, whose diameters are inversely as the tenuity of the threads.—Again, in a thin circular plate let a very small hole be bored, and all around it, at small distances, a series of similar circular holes. Place behind the central hole, the flame of a lamp, and examine the luminous point through some substance, that it is desired to examine. Around the central hole, a halo will appear, and by moving the substance under examination nearer to, or farther from the plate (also a graduated scale), this halo may be made to coincide with the ring of holes surrounding the central one. The distance of the object or substance from the ring must then be read off at the scale; and this distance will be a correct measure of the diameter of the fibres, or globules, of which the substance is composed. Young computed in this way the diameters of a great number of substances, such as the fibres of finest cambric, the globules of the blood, &c.

Errors. It has been already explained under CORRECTION, that no Observer ventures to assume that the results at which he arrives by aid either of his *senses* or *instruments*, can be accounted perfect. Imperfections inhere in his own *temperament*, and, it may be, in the *sense* he is using; and let the instrument be the best that ever came from Artist's hands, we may be well assured that it does not perform with absolute correctness any one of its professed functions. The

detection of the fixed errors, alike in his person and his instrument, is therefore a first duty of the Observer: and we have shown, under article already referred to, how allowances must always be made for such inaccuracies. This done, however, errors still remain, errors from accidental causes, or at all events of irregular origin, and not reducible to any law. For instance, suppose that the problem is to determine the exact position of some remote immovable point, the Observer finds that no two of his determinations exactly agree, neither do the observations of different observers. To insure the utmost attainable accuracy, observations are repeated on the point, and numbers of determinations accumulated; and the practical question is—in what manner, out of all these imperfect determinations, may the truth as to the required position, be deduced as accurately as possible? Two points bearing on this inquiry demand especial notice.—1. We shall here presume that the Observations to be dealt with, are, in so far as the Observer knows, equally good,—in other words, that he has no reason to place greater reliance on one set of them, than on another set. If this is not the case, the numbers given by the different observations must be first brought to a condition that will permit all being dealt with, as if it were the case. And for the mode of reduction, in this respect, the reader is referred to OBSERVATIONS, WEIGHT OF. The mode of combining a set of such equally probable Observations, in most general use, is, by taking what is termed their *average* or *mean*: i.e. the separate results are added together, and divided by their number,—a rule which holds as the best, in a certain number of cases, but by no means in all cases—not even in the largest and most important class. For instance, if the Observation belongs to a class of which the following may be taken as an illustration, the rule of the *Arithmetical mean* or *average* would be the true one. Suppose the Observer, seeking to deter-

Fig. 1.

mine the position of A, took five observations whose results gave him the points A^1, A^2, A^3, A^4, A^5 , &c. instead of A, then, assuredly, the most probable position of A as deduced from these results, would be that of an intermediate point, the sum of whose distances from A^1, A^2, A^3 , on the one side of it should just be equal to the sum of its distances from A^4 and A^5 on the other side; and this would be equivalent to the *Arithmetical Mean*. But suppose the points were not in a straight line, but scattered, as below, around A, in space, the *Arithmetical* rule would not directly apply. To find the most probable locality of A in this case, by aid of the principle

of the average, we should require to enclose the foregoing polygon within rectangular co-ordinates, and find the position of A with regard to each of them. But there is a

simple method,—one that contains the germ of the most general method, and which will be readily understood. The most probable position of A, will, in this case, be the *centre of figure*, or the *centre of gravity* of the polygon. But it is a property of the

Fig. 2.

centre of gravity of such a polygon, that the sum of the squares of these lines, $AA^1, AA^2, \&c. AA^5$, is less than the sum of squares of similar lines drawn from any other point to the angles of the polygon. These lines, $AA^1, \&c.$ are the *errors* of the separate observations; therefore, the rule for finding the average is simply this,—determine the mean point so, that the sums of the squares of the deviations of the separate Observations from it, or the *sums of the squares of the ERRORS shall be the least possible*. This is the root of that famous principle of the *LEAST SQUARES*, introduced by Gauss and Legendre, and now of universal acceptance. See SQUARES, THE LEAST.—2. The true mean, or average, thus determined, it is of greatest importance to know *how far* the mean may be supposed still to *diverge from the absolute truth*, or how near it may be supposed to *approach it*? In other words, what is the *probable Error* of the *Mean*? The rules above given apply to any set of Observations, limited or numerous, or whether made by a good or indifferent Observer. The *best Mean*, will in all cases be found by this rule; but the weight due to that mean, or the amount of reliance we can put on it, will, of course, vary with the circumstances just mentioned: and that variation may be expressed by the *probable error* of the *Mean*. It is clear that the value of the mean as to correctness, or its reliability, must depend on the nearness of the separate observations to it, whereas we shall measure its *unreliability*, or its probable *inaccuracy*, mainly by the remoteness of the separate observations from it. The following are the rules that guide us in our appreciation of all its qualities:—the demonstration of these rules is found in every good treatise on *Probabilities*. The qualities of a result obtained as above, that need to be determined, are its *precision*, its *weight*, its *probable error*, and its *mean error*. Taking m as the mean square of the errors, these qualities are determined by the following formulæ:—

$$\text{Precision} = \sqrt{\frac{1}{2m}}$$

$$\text{Weight} = \frac{1}{2m}$$

$$\text{Probable Error} = .674489 \sqrt{m}.$$

$$\text{Mean Error} = .398942 \sqrt{m}.$$

Eudiometer. An instrument chiefly of chemical interest, originally employed in the analysis of atmospheric air;—a result of Priestley's great discovery of the non-homogeneous nature of airs and gases. It was thought for a long time air and gas was one simple substance. Priestley discovered that in atmospheric air there are at least two sorts of substances. The Eudiometer is an instrument invented for the sake of analyzing air quantitatively as well as qualitatively—that is, obtaining the knowledge how many proportions of each different element, a given quantity of air (e. g. 100 parts) contains. The principle is generally that of presenting some body to the oxygen of the air or other gas (for they are employed for analyzing all gases), which may be capable of taking it up completely, leaving the others free. The details are entirely chemical. See *Penny Cyclopædia* and *Thomson's Cyclopædia of Chemistry*.

Eunomia. One of the Asteroids. For Elements, &c., see ASTEROIDS.

Evaporation. It appears that every substance, *solid* or *liquid*, tends to convert itself, to an extent depending on the temperature and other circumstances, into invisible vapour: water, for instance, sends off vapour from its surface at all temperatures, even when it is ice. This process is termed *Evaporation*: *Vaporization*, as distinguished from evaporation, signifies the conversion of a liquid into vapour by the mode of *ebullition*. It appears that all vapours enjoy the property of gases, in mixing with other aeriform fluids, according to their own laws, and as if they were diffused through a void. Every special atmosphere of vapour within our compound atmosphere, therefore, acts on its own particles alone: i. e. the aqueous vapour in the air acts by pressure only on itself. The limit to evaporation is therefore this; if an amount of vapour has already accumulated in the air, so that its weight equals the elastic force of vapour at the temperature of the surface of the exposed liquid, no more vapour will rise from that surface; and, *cæteris paribus*, the rapidity of evaporation will depend on the amount by which the weight of the vaporous atmosphere is less than this elasticity. The second main physical character of evaporation is this—it cannot take place without producing *cold*. A body in the state of vapour has a much greater capacity for heat, than when in the condition either of liquid or solid; the change of state necessarily causing absorption of heat, by the vapour, from all sur-

rounding bodies:—a fact readily illustrated if one pours a few drops of ether, or any liquid of rapid evaporation, into the palm of the hand. If the evaporation proceed with great rapidity, this absorption becomes sufficiently powerful to produce noticeable effects. Evaporation of ether *in vacuo*, may be made to freeze mercury: ice is formed in Leslie's beautiful experiment, under the receiver of an air pump, by the evaporation of water itself: by the same power of rapid evaporation, carbonic acid gas was solidified by Thilorier, and Boutigny has recently shown us ice produced by the same energy in an *incandescent crucible*! The icy caverns of the Jura, the ice cavern of Connecticut, as well as that remarkable one of Illetzkaya, in the steppes of the Kirghis, owe their frigorific character to intense evaporation of moisture caused by the adjacency of the warm and dry external air: but it is among the general phenomena of Meteorology that this important agency plays its most conspicuous part. The reader is referred to HYDROMETEORS, HYGROMETRY, METEOROLOGY, and VAPOURS.—Instruments of several simple forms are used to note the rate of Evaporation, as an element in the meteorological character of the time of observation.—See further, HEAT, sec. 19.

Evaporation, Mechanical Theory of. In various parts of this Cyclopædia proofs are advanced of the truth of the modern theory that those affections of substances, which we term their relations to heat, spring from motions of their molecules. The inferences from this theory, in reference to evaporation, are curious and interesting, and are intended to be briefly explained in the present article.—The nature of the motions of the molecules of substances, in different states of aggregation—solid, liquid, or gaseous—is of course not as yet matter of experiment, and has been variously conceived; some, with Professor Rankine, prefer the vortical theory; others lean to the idea of a motion of translation or oscillation. Without rejecting the notion of vortices, which also will account for most of the phenomena, *Joule*, in 1848, represented the possible state of gases as a state in which the molecules are in rapid translation, impinging on each other like elastic balls, and finally on the sides of a vessel containing them, with a force represented by their elastic or expansive energy. Taking hydrogen gas as an example, he computed that the velocity of its particles at 60° F., and a barometrical pressure of 30 inches, must be 6,225 feet per second. *Krönig* and *Clausius* afterwards worked under the same conception.—The condition of the molecules of a liquid must be more complex and less easily realized. They may be turning round their centres of gravity, and these centres may also be moved out of their place, or have a limited motion of translation. In fact, a rotating, an oscillating, and a translatory motion may all take place simultaneously, although in

such a manner that these molecules are not thereby separated from each other, but remain within a certain volume. Let us now contemplate the state of the surface of a liquid thus constituted. Amongst those varied motions of its molecules to and fro—which must be *individually* irregular, although their *mean* is constant—it can scarcely happen otherwise than that, under a favourable co-operation of all its constituent motions (translatory, oscillating, and rotating), a molecule will separate itself with violence from its neighbours, and receding from the sphere of their action, continue its flight into the space above the liquid. Suppose that space enclosed, and empty,—it will gradually become more and more filled with such molecules, which, having assumed the motions of the molecules of a gas, will strike, as already described, on all the enclosing surfaces. But the liquid is one of these surfaces; and when a molecule strikes against that, it will most probably be absorbed or retained, in consequence of the renewed attraction of the other molecules into whose vicinity it has been driven. A state of equilibrium will ensue when the number of molecules in the enclosed space is such that, on the average, as many strike against the surface of the liquid as are expelled from it in the same time. This equilibrium, therefore, is not a state of rest or of the cessation of evaporation, but a state in which evaporation and condensation continually take place, and compensate each other in consequence of their equal intensity. The density of the vapour necessary for this compensation is evidently dependent upon the number of the molecules expelled from the surface of the liquid in the unit of time—i. e., on the activity of the motions within the liquid; in other words, upon its temperature.—It is easy to see that the foregoing change of motion must be accompanied by the disappearance of a large amount of thermometric heat.—Clausius, to whom we owe the previous speculation, proceeds to explain why the presence of another gas above the liquid cannot impede its evaporation. The pressure of the gas on the liquid arises solely from the fact that, here and there, single molecules of the gas strike against the liquid's surface. But, inasmuch as these actually fill but a small part of the space, that space may virtually be considered as empty, and offering a free passage to the molecules of the liquid. "In general, these molecules will come into collision with those of the gas only at comparatively great distances from the surface, and the former will then deport themselves towards the latter, as would the molecules of any other admixed gas. We must conclude, therefore, that the liquid also expels its molecules into the space filled with gas, and that in this case also the quantity of vapour thus mixed with the gas continues to increase, until, on the whole, as many molecules of vapour strike against, and are absorbed by the surface of the liquid, as the

latter itself expels: so that the number of molecules of vapour to the unit of volume requisite thereto, is the same, whether the space does or does not contain additional molecules of gas." It will be easily seen, however, that the pressure of the new or foreign gas exercises a very different influence on the *interior* of the liquid.—As in *liquids*, so in *solids*—the possibility of an evaporation may be comprehended; nevertheless, it does not follow from this that an evaporation ~~must~~ take place on the surface of all bodies. It is, in fact, readily conceivable that the mutual cohesion of the molecules of a body may be so great, that so long as the temperature does not exceed a certain limit, even the most favourable combination of the several molecular motions is not able to overcome this cohesion. It will be readily seen that the theory now given quite concurs with the older speculations of Faraday.—Joule's memoir, to which we have referred, was read to the Manchester Philosophical Society on October 8, 1848, and is republished in the *Philosophical Magazine and Journal* for 1857, vol. ii. Krönig's work is entitled *Grundzüge einer Theorie der Gase*. The very interesting memoir by Clausius, "On the Nature of the Motion which we call Heat," is reprinted in the volume of the *Philosophical Magazine* just mentioned.

Evection. A lunar inequality. See LUNAR THEORY.

Evolute. A term correlative to *involute*—applied to a curve. One curve is the evolute of another when it is formed by unrolling a thread wrapped round this first curve; and to the end of which thread a pencil is attached. The involute is the curve from which the evolute is formed—the one round which the thread is wrapped. It is evident that any given curve can only have one evolute; but it is also manifest that the same evolute may be traced from many involutes. One can easily trace the evolute of a circle by taking a crown piece and unwrapping a thread as described. The circle may itself be considered as the evolute of a point. Any curve may have an infinite number of involutes. The mathematical equations which connect the evolute and involute are the following: Let

$$y = \phi x,$$

be the equation of the Involute; then

$$(x - x) + (y - y) \frac{dy}{dx} = 0.$$

$$1 + \left(\frac{dy}{dx} \right)^2 - \frac{d^2y}{dx^2} (y - y) = 0.$$

From which x and y , being ordinates of the involute, must be eliminated. If the evolute be given and the involute be required, then $y = f x$ must be used instead of the first equation, and from this with the other two the ordinates of the evolute x and y must be eliminated, giving a differential equation of the second order for the involute, with no means of determining the con-

stants. The number of involutes of a given evolute is therefore infinite.

Evolution. An algebraic term correlative with *involution*. In the technical sense in which the two words are commonly used they mean the *extraction of roots*, and the *raising to powers*. When any number, as 5, is multiplied by itself, we obtain 25, the *second power*, or *square* of 5. By another multiplication we obtain the *third power*, or *cube*; by still another, the *fourth power*, and so on, the name of the power corresponding to the number of recurrences of the quantity. Thus, $5 \times 5 \times 5 \times 5 \times 5$, is the *fifth power* (3125) of 5. This continual multiplication is called *involution*. Suppose now that we have the number 3125 before us, and that we are required to find a number, such that when it is thus multiplied 5 times into itself, the result will be 3125 i.e.:—to find the *fifth root* of 3125. We chanced to know that the result at present is 5, but when we do not, as is oftentimes the case, we have to enter into complicated processes to determine it. These processes are called *evolutions*. A more extended meaning has been given to the terms, according to which they are thus defined:—Involution is the performance of any number of successive multiplications with the same multiples, interrupted or not by additions or subtractions; and evolution is any method of finding out from the result of an involution what multiplier was employed, provided that the said method proceeds by involutions. Thus $[(2x + 4)x - 3]x + 10$, is the result of *involution*, which consists in the performance of the operation indicated. The deduction from the simple result, $2x^2 + 4x^2 - 3x + 10$, that those operations have been performed, is what *evolution* consists in. This extension of the term makes the theory of equations a branch of evolution, as unquestionably it ought to be considered. For the discovery that a certain quantity is equal to (e.g.) $10^a \times a + 10^b \times b + 10 \times c + d$, &c. though a little less complex in practice, depends on the very same principle as the more general question of evolution. In its more confined sense—in the obtaining of powers and roots of arithmetical quantities—Barlow's table of square and cube roots is invaluable to all who have many arithmetical calculations to make. In physical inquiry it is constantly required to extract roots, or to raise to powers, and the waste of time in going through very long processes would be enormous. Such tables are not only useful for determining square and cube roots, and second and third powers, but also for determining all other powers and roots by simple rules. The simple formulæ applied for these are, $(a^n)^m = a^{nm}$, and $a^n \times a^m = a^{n+m}$, for involution; and for evolu-

tion, $\sqrt[n]{a^m} = a^{\frac{m}{n}}$, and $\frac{a^{\frac{1}{n}}}{a^{\frac{1}{m}}} = a^{\frac{1}{n} - \frac{1}{m}} = a^{\frac{m-n}{nm}}$.

Thus, the sixth root of 15625 may be thus found, $15625^{\frac{1}{6}}$

$$= \sqrt[6]{15625^{\frac{1}{2}}} \left(\frac{1}{a^{\frac{1}{2}}} = \sqrt{\frac{1}{a^2}} \right) = \sqrt{125} = 5.$$

Again, the sixth power of 5, may be thus found,

$$5^6 = 5^2 \times 5^2 = 125 \times 125 = 15625$$

$$(a^m + n = a^m \times a^n); \text{ or thus, } 5^6 = (5^2)^3 = (125)^2 = 15625 [(a^n)^m = a^{nm}].$$

Exhaustions, Method of. The process by which the Greek Geometers passed from the areas, &c. of *rectilinear* figures to those of *curvilinear*. The latter class of questions could not, on the ground of the accepted principles of the ancient Geometry, be treated directly, or unless through such a transition; and the method of Exhaustion was the logical process of that transition. The process referred to must be carefully distinguished from one of mere approximation: the results it demonstrates are fully and rigorously demonstrated. The Greek Geometer, for instance, was not satisfied with showing that we could come as near as possible, or nearer than any given finite quantity, to the area, let us say of a circle, by increasing indefinitely the number of the sides of inserted polygons. It is true that a polygon might thus be conceived, differing from the circle by a quantity less than any that could be stated; and it might seem quite allowable to transfer any general property of the polygon to the circle itself, or to consider the two identical: but this would not have satisfied the critical spirit of these exquisite reasoners. And that there might be no *lacuna* whatsoever, or the substitution of a mere approximation for the absolute truth, Euclid—in all probability—*first* sought to make the transition absolutely legitimate;—resting it on the two following propositions.—1. If from A, more than its half be taken, and from the remainder more than its half, and so on, the remainder will at last become less than B, where B is any similar magnitude named at the outset and however small. 2. Let there be two magnitudes, P and Q, both of the same kind, and let a succession of other magnitudes, which we may call P_1, P_2, P_3 , be each nearer and nearer to P, so that any one, P_2 , shall differ from P less than half as much as its predecessor differed. Let Q_1, Q_2, Q_3 , &c. be magnitudes of the same kind in regard to Q: and let the ratios of $P_1 : Q_1$ of $P_2 : Q_2$, &c. be all the same ratio,—the ratio, we shall say, of A : B; then must the ratio of P : Q be that of A : B. It will easily be seen by the student, that if P and Q be two circles, P and Q inserted squares, P_2 and Q_2 inserted octagons, &c. and A and B the squares in the diameters of the circles—it will follow at once that $P : Q = A : B$.—The Method of Exhaustions had the same relation to the modern Method of *Limits*, as the Method of *Indivisibles* to the *Infinitesimal* Method of Leibnitz.

EXP

Expansion. The two forces which chiefly operate in maintaining the old, or causing a new state of aggregation in bodies, as solid, liquid, or gaseous, are the forces of *cohesion* and *heat*. The latter is the disuniting principle, tending to render solids liquid or gaseous, and liquids gaseous. The former principle produces the reverse effect.—A certain amount of *heat*, however, is required to produce such change of aggregate condition; and quantities short of this, may be expected to produce some change, though not one so complete. In fact, heat does expand bodies, i.e. it drives the particles farther from another, before it produces a change of state; and this phenomenon is called *expansion*. The methods of measuring expansion are detailed in the articles PYROMETER and THERMOMETER; and we shall proceed here to give some of the results of measurement, assuming these methods to be known.—We should expect to find, and actually do, that in consequence of the difference of molecular constitution in solids and liquids and gases, there are great differences also in their capacities for expansion, and in the amounts of it under different circumstances.—In experimenting on solid bodies, it is most usual to heat long prismatic bars through certain ranges of temperature, and watch their increase of length. An important deduction from the *fact* of expansion is the danger of embedding metals—bodies readily expanding or contracting—in buildings, the stone and wood of which expand but little. In winter, the metal draws the stone towards itself, by contraction, and in summer, pushes it away—so, breaking up the stone. If the metal cannot quite free itself from its connection, it will destroy the building. Several buildings have required to be taken to pieces, because the architect very imprudently made use of iron bars for increase of security.—The amount of this expansion, as we have said, is usually measured by the dilatation in length, of rods of the substance in question, heated through a given range of temperature. Such a method is evidently very convenient, as the amount wanted, is capable so of easy measurement. But in liquids and gases we cannot employ it. We cannot take a bar of air or water, and measure how much longer it becomes, under a given amount of heat. We must, therefore, find some relation between the methods of measuring expansion by linear dilatation, and increase of volume. Suppose a rectangular prismatic bar, whose length, breadth, and thickness are a , b , c , respectively. Its contents will bear a certain ratio to the regular cube a^3 . If it be expanded, it will continue to bear the same ratio to the cube of the side corresponding to a , for all parts expand proportionally. Hence, if h be the linear dilatation of a , the new length will be $a+h$, and the ratio of the contents or volumes will be $a^3 : (a+h)^3$. The measure of linear dilatation is then $\frac{(a+h)-a}{a}$, and of cubical ex-

EXP

pansion $\frac{(a+h)^3 - a^3}{a^3}$, the first equal to $\frac{h}{a}$ and the second to $\frac{h^3 + 3ah^2 + 3a^2h}{a^3}$, or to $\frac{h}{a} + \frac{3h^2}{a^2} + \frac{h^3}{a^3}$. Now, in all cases of solid expansion, $\frac{h}{a}$ the linear dilatation is a very small fraction. Thus, for *tin* heated from 82° to 212° , it is only 1-462. The ratio of cubical expansion to linear dilatation, which is $\left(\frac{3h}{a} + \frac{h^3}{a^3}\right) \div \frac{h}{a}$, or $3 + \frac{h^2}{a^2}$, differ very little,

indeed, from 3, and we may take this rule when we are not requiring exactness within, perhaps, 1-150th of the whole quantity measured, that the cubical expansion may be found *by trebling the linear dilatation*.—In measuring the amount of such expansion, in any case, the great difficulty is to avoid errors in the detection of a quantity so small. The methods employed to magnify the visible result are in principle the same as this one. The bar, AB (see figure) is heated, and expands.

It is kept firmly fixed at one end, and at the other end pushes against the short end of a lever. The long end moves through a space so much larger than the bar and the short one which moves with it, as it is longer than the short one. If this long end move the short end of another lever, we may have the required quantity again multiplied, and so indefinitely. This same principle of multiplying small motions by levers, in order that they may become more easily measured, is very frequently employed in similar determinations.—Another requirement in making such measures, is, that the moving bar be uniformly heated, so that the real dilatation of the bar may be due to precisely the amount of heat which you measure. Lamps arranged under it, at equal distances, are sometimes employed for this, but the more usual, and much the better method, is to place it in a vessel of liquid, at one extremity of your temperature range, leaving it there till it gets time to take its temperature exactly, and then heat the liquid up to the other extremity of your temperature range, giving the bar time to assume perfectly the same temperature also. Taking this last method, the following measures of linear dilatation are obtained:—

This table gives, pretty accurately, the observed dilatations within the range of temperatures, 32° and 212°. When we proceed to apply it to other temperatures, however, we find it at fault; the cause being, that the amount of dilatation is not the same for equal increase of measurable temperature from different starting points. It requires a different amount of heat—less considerably—to raise a body from 212° to 218°, than from 32° to 38°. The cause of this one can understand. In solids, there is a balance of cohesive and expansive forces. After these latter become considerably developed, the particles of bodies are much farther distant than before. Now, cohesion, like all other forces that we know of, diminishes with distance, and therefore, new heat, in causing still farther separation of the particles of bodies, has to act against considerably less resistance than before. It accomplishes more sensible work, therefore, i.e. gives a larger dilatation. The subject has not been much experimented upon, but the following few results are trustworthy:—

	Linear dilatation in rise from 212° to 218°	and from 572° to 578°
Glass	1-69680	1-59220
Platinum	1-57860	1-65840

Copper	1-34120	1-31860

As platinum is here least irregular in its expansion, giving dilatation most nearly equal for

EXP

the equal rise of temperature, it would be best fitted for a metallic thermometer.—The difference in the rates of expansion of metals can be employed as a very delicate thermometric means. Two metals are combined which expand differently, and this difference is measured. Breguet's thermometer is an admirable illustration of this. See THERMOMETER.—We have said that the rate of dilatation is increased for equal ascents from increased temperatures. This is generally, but not always true. Sometimes, on the contrary, the expansion takes a turn downwards, and the body, if heated further, will expand, but will also do so if cooled down. In passing, therefore, up to this point of greatest density, it has contracted instead of expanded. This property exists also in liquids, as we shall immediately see. Of solids, the one which best exemplifies it is that called Rose's fusible metal, which, when heated from 82° to 111°, expands from 100 to 100·88 parts. On heating from 111° to 156°, the body contracts instead of expanding, until at 156°, the body is only 99·291 in volume. From 156° to 178° it expands, rising to 100, and from 178° up to 201°, continues to expand, reaching 100·862 parts, and there it begins to melt. It is curious that the body has no point of maximum density when in this liquid state, as most other liquids have.—Passing to the expansion of liquids, we find this same phenomenon. When a liquid is heated from a certain point, it frequently—although not always—contracts, instead of expanding, and expands in coming down from that point. The general law seems to be, as in solids, that the amount of dilatation for equal rises of temperature is greater the greater the initial temperature is. The explanation is probably quite the same as that given for solids, that there is a diminished cohesive force, against which the expansive power of heat must act. The amount of expansion of some liquids in passing through 180° Fahr. is herewith given. Alcohol, 1-9—Nitric Acid, 1-9—Fixed Oils, 1-12—Sulphuric Ether, 1-14—Oil of Turpentine, 1-14—Sulphuric Acid, 1-17—Water, 1-28—Mercury, 1-55. In comparing the expansions of liquids, it has been well noted by Guy Lussac, that we must take them at the same point where the cohesive forces act similarly; since these so modify the visible results due to the expansive forces. Taking this principle, we find such tables as the following. The starting point in each case is the boiling point of the liquid, for Water, 212°; for Alcohol, 173°; for Sulphuret of Carbon, 184°; for Sulphuric Ether, 96°·8. Taking 1,000 volumes of each, and allowing them to cool—

EXP

The remarkable coincidence in the contractions of alcohol and sulphuret of carbon, here given, shows a similarity, probably an identity, of molecular constitution. The forces which bind two such dissimilar bodies together must act in the same way, and the discovery of such a relation is only one instance of the value of the principle. A glance at this table will show the reader that the law of increase of dilatation with temperature, already noticed in solids, holds here also.—It must be remembered in comparing such expansions and contractions with those given for solids—that in the latter *linear* dilatation, *here* *cubical* expansion is noted. The method of reducing the one to the other has been sufficiently indicated.—The fact of a maximum density in many liquids was first noticed in water; and its value in the economy of nature can be best seen by it. If ice were heavier than water, as water at 39° is heavier than water at 40°, ice would be found only at the bottom of our streams, or rather, formed in its passage to the bottom, would sink to it, and when a sufficient degree of cold was obtained, they would freeze up from the bottom, making the whole water one solid mass. As it is, ice at 32° is lighter than water, and water at lower temperatures below 39° is lighter than water at higher temperatures still below that point, and therefore in the process of freezing, the water which is sinking in temperature from 39° to 32° keeps at the top, and when ice is formed it is on the top and remains there. Now ice does not transmit heat very well—not nearly so well as water, and the warmth of the water below is therefore not so quickly given away to the cold spaces above as it would otherwise be—(scarce at all by conduction through ice, and in neither case much by radiation), or if the ice were at the bottom and the warmer water was in direct contact with the air. The complete freezing of our rivers and many of our seas, probably uncompensated by corresponding thaws in summer, would render navigation most difficult or altogether impossible except in the seas of the temperate and torrid zones. The same property is quite as noticeable, however, in other bodies as in water. In fact most liquids, in passing to the solid state, exemplify it. Thus melted metals poured into a mould would give no impress of it if they contracted constantly as they cooled—or by no means so good a one as they now do. From certain points of temperature they are expanded in cooling, and their expanding mass presses with great violence against the sides of the mould. The theory, which alone seems to give plausible explanation of the phenomenon—and which is still, unfortunately, a mere theory, is this, that such bodies *crystallize* before we see them do so. Now, bodies crystallizing take up generally more space than before. The peculiar constitution of crystalline bodies does not admit of great economy of space. The particles assume a definite arrangement, and vacua result in the

EXP

spaces which they prevent each other from filling up. Hence it is natural that bodies expand in crystallizing, even though the cold under which they do so, tends to make them contract. If the theory be true, the amounts of heat given off by the fluid during the expansion of cooling ought to be considerably greater than for equal diminutions of temperature at other points of the scale—just as in the actual crystallization of ice there are 142° of heat given out without any noticeable lessening of the temperature. One considerable difficulty in the way of this hypothesis is its seeming inadequacy to explain the perfectly analogous phenomenon of Rose's fusible metal. The liquid and the solid have maximum densities in all likelihood for the same physical reason, and it does not seem possible to suppose crystallization in the process of cooling from 156° to 111°, while it does not take place from 110° to 82°, nor from 211° to 156°. Until some physical fact more than the mere expansion due to crystallizing can be brought forward, it must remain a hypothesis, with no other value than as indicating a direction in which researches should be carried on. As the amount of expansion of water for the ordinary range will give a notion of the like expansion in other bodies, and is besides of very great interest in itself, we give Despretz's table of its volumes for increase of 1° at each successive degree:—

Cent.	Fahr.	Volumes.	Cent.	Fahr.	Volumes.
9°	15.8	1.0016311	34	93.2	1.00555
8	17.6	1.0013734	35	95	1.00593
7	19.4	1.0011354	36	96.8	1.00624

The maximum of density in water is therefore about 4° centigrade, or 39.2 Fahr. degrees. In sea water it is 25.39 Fahr. In alcohol 36.14. In sulphuric acid of different strengths it ranges from 30.92 to 26.534, and so on for other liquids. —In gases the laws of expansion are much more simple. This is precisely what we should expect. All gases are in the same condition as regards the cohesive forces;—the cohesive force being simply non-existent in them. Hence the expansive force of heat does not act against a resistance growing weaker and weaker every moment, but not against any resisting force at all. We should expect from this want of cohesion that all gases expand alike for given increase of heat; as each gas does expand alike for equal increase of heat to itself when rising from different temperatures. It was long supposed that this was the case; but the singularly accurate investigations of Regnault have proved the incorrectness of the notion. Thus common air expands, under certain pressure, from 1,000 volumes to 1,366 in passing from 32° to 212°, and in the same passage 1,000 volumes of carbonic acid become 1,371, of nitrous oxide 1,372, of cyanogen 1,388, of sulphurous acid 1,390. These results lead us to infer that the usual postulate that the particles of gases do not at all act upon one another so as to resist expansion, is somewhat hasty; and the subject offers an admirable field for further investigation and for enlarged theoretical views. It is worth notice that those gases are most expandible which, when subjected to pressure, liquefy most readily. Thus, sulphurous acid liquefies under a pressure of two atmospheres, and expands 390 thousandths of its bulk in passing up from 32° to 212°. Carbonic acid again takes 86 atmospheres to liquefy it, and accordingly only expands 371 thousandths of its bulk, while ordinary air, quite incapable of liquefaction, by a pressure at all events of 800 atmospheres, only expands 366 thousandths of its bulk. This remarkable agreement in nature it is not easy to represent in theory. It should follow that there is certain molecular action between the particles of gases besides the ordinary repulsive action attributed to them, and that there may be different amounts of dilatation for the same rise of temperature from different points on the thermometric scale. In fact we actually find such differences. Thus in expanding from—33° to 32° Fahr., 8,650 volumes of air become 10,000,

EXP

and there is for every rise of a degree an expansion of 20.77 ten thousandths. From 32° to 212°, the 10,000 parts become 13,750, being 20.83 for a degree. From this to 300° they become 15,576, being 20.70. From this to 387° we get 17,389, or 20.82 per degree. From this to 473°, 19,189, or 20.84. From this to 559°, 20,976, or 20.88, and from this to 660° they become 23,125, or 20.9 for a degree. These results, though not quite accurate, as later experiments by Rudberg, Magnus, and Regnault have shown, sufficiently indicate the result. These latter, which are very accurately made and may be fully relied on, give 2.033 thousandths or $\frac{1}{492}$ as the

cubical expansion of air for each rise of a degree between 32° and 212°. For each rise elsewhere also; for the differences, as the above list shows us, are very small and almost inconsiderable. In consequence of this, the volume of a gas obtained by measurement at a given temperature must either be stated along with the temperature (e.g. 20ft. hydrogen gas at 60°), or must be corrected for variations of its heat, and reduced to the volume which would be occupied at a given temperature. Taking atmospheric air as an example, a volume, say 100 cubic inches of air at 182°, must be reduced to so many at 32°, when we wish to compare its volume with a series of such volumes.—In connection with this subject, it may be proper to notice here that the steam engine was originally driven by steam of not very high pressure, which was kept pouring into the piston during the whole stroke. It was found economical to use high pressure steam instead of low pressure steam, prepared as in Papin's digester. See DIGESTER. This, however, could not be let in during the whole stroke, for it would send the piston alternately against the top and bottom of the cylinder with a violence that would cause great inconvenience in any building in which the engine might be placed. Besides, there would be an enormous proportion of the work of the engine used in merely producing this mischievous effect. It was evident, therefore, that (even with low pressure engines) this must somehow be stopped. This knocking of the piston on the ends of the cylinder did much harm to the machine, and cost a large part of the fuel. The idea was suggested to Watt, that in order to prevent it it might be possible to admit the steam for only half the stroke. This would give a certain amount of velocity to the piston rod, and when the steam was cut off that velocity would continue diminishing if all force upon the rod were immediately to cease. But in the ordinary engine the piston is pushed towards vacuum, or rather against a resistance something like 4 or 5 lbs. per square inch. Now the steam admitted into the cylinder in an engine may be, suppose of 20 lbs. pressure per square inch. Let it be cut off after one-fourth of the stroke of the piston is accomplished. Then by Mariotte's law,

EXP

it goes on through the rest of the stroke constantly diminishing in elastic force. At one-half of the stroke it has come to have a pressure of only 10 lbs. per square inch—half of what it was left with. In coming up to the end of the next quarter it lowers its pressure to $6\frac{1}{2}$ feet, and at the top it has a pressure of 5 feet. In the first quarter of motion then, the piston has moved, because of the excess of the one pressure 20 lbs. over the other, 5 lbs. per square inch, and therefore has moved with an effective pressure of 15 lbs. per square inch through it. This gives it a very considerable velocity, which it is its tendency to keep and the tendency of the friction and other causes to destroy. During the next quarter it moves with an excess of pressure diminishing from 15 to 5 lbs., but always acting in the same direction. As the piston tends of itself, without any pressure, to keep its old velocity, this constant pressure will probably be sufficient to increase the velocity, though the steam has been cut off, and the body tends again to go on with this velocity. During the next quarter the excess, still in the same direction, goes down from 5 to $1\frac{1}{2}$ lbs. per square inch, and this is perhaps sufficient in ordinary engines to prevent the friction from diminishing the velocity with which the piston started in this quarter, and in the next quarter it will go down from $1\frac{1}{2}$ lbs. to zero, and be perhaps capable of preventing any very rapid decrease of velocity, certainly letting the body be carried up fully to the end. Here, therefore, only one-fourth of the steam has been used and the same motion produced. The same velocity indeed has not, but if the steam which enters came with a pressure of 30 instead of 20 lbs., there would be quite as much of this velocity obtained, while the employment of steam of that pressure, desirable on account of its economy, is not possible with the old methods. Such is the principle of expansion, without which the modern steam engine would be a clumsy and inconvenient contrivance, and to which chiefly are due all that perfect quietness of movement which is so wonderful to those who see for the first time the engines of a first-rate steamer at work. An idea of the value of this contrivance in point of economy may be conceived from this table:—

If the steam be stopped at the piston stroke	The performance is multiplied by
One-half.....	1.7
One-third.....	2.1
One-fourth.....	2.4
One-fifth.....	2.6
One-sixth.....	2.8
One-seventh.....	3
One-eighth.....	3.2

Methods of calculating the value of this economy more accurately depend upon the higher mathematics; but the above table will give the reader a notion how much can be thus done. The simplest general rule we can give is, that the proportions of work done by the same fuel are expressed as equal

EYE

to $1 + \text{Neperian log } (1 + \frac{1}{4})$, taking for example the case of steam cut off at one-fourth of the stroke; and always taking, instead of 4, the reciprocal of the fraction of the stroke through which the steam is freely admitted. The importance of the utmost economy of fuel for mercantile purposes, and especially for the purposes of steam navigation, has been already dwelt upon at length in the article AIR ENGINE (*q.v.*) See further ELASTICITY; and HEAT, sections 10, 14, 16, and 18.

Exponent. The number indicating the degree of power or a root. Thus in x^8 , 8 is the exponent of the given power of x , and $\sqrt[4]{x}$, 4 is the exponent of the given root. Descartes originated the use of exponents. Before his time the quantity a^8 would have been written $a a a$.

Exponential. Quantities representing powers whose exponents are variable. Thus a^x is called an exponential. Quantities in the expression of which such a simple quantity is contained are also so called.
